

Welcome

This is the website for the work-in-progress 2nd edition of “**R for Data Science**”. This book will teach you how to do data science with R: You’ll learn how to get your data into R, get it into the most useful structure, transform it and visualize.

In this book, you will find a practicum of skills for data science. Just as a chemist learns how to clean test tubes and stock a lab, you’ll learn how to clean data and draw plots—and many other things besides. These are the skills that allow data science to happen, and here you will find the best practices for doing each of these things with R. You’ll learn how to use the grammar of graphics, literate programming, and reproducible research to save time. You’ll also learn how to manage cognitive resources to facilitate discoveries when wrangling, visualizing, and exploring data.

This website is and will always be free, licensed under the [CC BY-NC-ND 3.0 License](#). If you’d like a physical copy of the book, you can order the 1st edition on [Amazon](#), or wait until mid-2023 for the 2nd edition. If you appreciate reading the book for free and would like to give back please make a donation to [Kākāpō Recovery](#): the *kākāpō* (which appears on the cover of R4DS) is a critically endangered native NZ parrot; there are only 252 left.

available translations of the 1st edition:

- [Spanish](#)
- [Italian](#)
- [Turkish](#)

Please note that R4DS uses a [Contributor Code of Conduct](#). By contributing to this book, you agree to abide by its terms.

R4DS is hosted by <https://www.netlify.com> as part of their support of open source software and communities.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

Welcome to the second edition of “R for Data Science”! This is a major reworking of the first edition, removing material we no longer think is useful, adding material we wish we included in the first edition, and generally updating the text and code to reflect changes in best practices. We’re also very excited to welcome a new co-author: Mine Çetinkaya-Rundel, a noted data science educator and one of our colleagues at Posit (the company formerly known as RStudio).

A brief summary of the biggest changes follows:

- The first part of the book has been renamed to “Whole game”. The goal of this section is to give you the rough details of the “whole game” of data science before we dive into the details.
- The second part of the book is “Visualize”. This part gives data visualization tools and best practices a more thorough coverage compared to the first edition.
- The third part of the book is now called “Transform” and gains new chapters on numbers, logical vectors, and missing values. These were previously parts of the data transformation chapter, but needed much more room.
- The fourth part of the book is called “Import”. It’s a new set of chapters that goes beyond reading flat text files to now embrace working with spreadsheets, getting data out of databases, working with big data, rectangling hierarchical data, and scraping data from web sites.

- The “Program” part continues, but has been rewritten from top-to-bottom to focus on the most important parts of function writing and iteration. Function writing now includes sections on how to wrap tidyverse functions (dealing with the challenges of tidy evaluation), since this has become much easier over the last few years. We’ve added a new chapter on important Base R functions that you’re likely to see when reading R code found in the wild.
- The modeling part has been removed. We never had enough room to fully do modelling justice, and there are now much better resources available. We generally recommend using the [tidymodels](#) packages and reading [Tidy Modeling with R](#) by Max Kuhn and Julia Silge.
- The communicate part continues as well, but features Quarto instead of R Markdown as the tool of choice for authoring reproducible computational documents.

Other changes include switching from magrittr’s pipe (`%>%`) to the base pipe (`|>`) and switching the book’s source from RMarkdown to Quarto.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

1 Introduction

>

Data science is an exciting discipline that allows you to transform raw data into understanding, insight, and knowledge. The goal of “R for Data Science” is to help you learn the most important tools in R that will allow you to do data science efficiently and reproducibly. After reading this book, you’ll have the tools to tackle a wide variety of data science challenges using the best parts of R.

1.1 What you will learn

Data science is a vast field, and there’s no way you can master it all by reading a single book. This book aims to give you a solid foundation in the most important tools and enough knowledge to find the resources to learn more when necessary. Our model of the tools needed in a typical data science project looks something like [Figure 1.1](#).

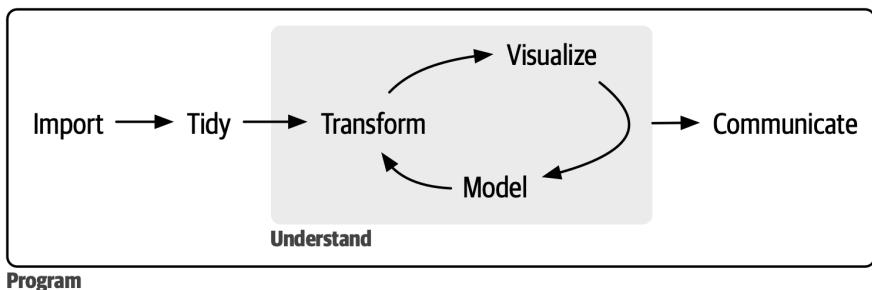

Figure 1.1: In our model of the data science process, you start with data import and tidying. Next, you understand your data with an iterative cycle of transforming, visualizing, and modeling. You finish the process by communicating your results to other humans.

First, you must **import** your data into R. This typically means that you take data stored in a file, database, or web application programming interface (API) and load it into a data frame in R. If you can't get your data into R, you can't do data science on it!

Once you've imported your data, it is a good idea to **tidy** it. Tidying your data means storing it in a consistent form that matches the semantics of the dataset with how it is stored. In brief, when your data is tidy, each column is a variable, and each row is an observation. Tidy data is important because the consistent structure lets you focus your efforts on answering questions about the data, not fighting to get the data into the right form for different functions.

Once you have tidy data, a common next step is to **transform** it. Transformation includes narrowing in on observations of interest (like all people in one city or all data from the last year), creating new variables that are functions of existing variables (like computing speed from distance and time), and calculating a set of summary statistics (like counts or means). Together, tidying and transforming are called **wrangling** because getting your data in a form that's natural to work with often feels like a fight!

Once you have tidy data with the variables you need, there are two main engines of knowledge generation: visualization and modeling. These have complementary strengths and weaknesses, so any real analysis will iterate between them many times.

Visualization is a fundamentally human activity. A good visualization will show you things you did not expect or raise new questions about the data. A good visualization might also hint that you're asking the wrong question or that you need to collect different data. Visualizations can surprise you, and they don't scale particularly well because they require a human to interpret them.

The last step of data science is **communication**, an absolutely critical part of any data analysis project. It doesn't matter how well your models and visualization have led you to understand the data unless you can also communicate your results to others.

Surrounding all these tools is **programming**. Programming is a cross-cutting tool that you use in nearly every part of a data science project. You don't need to be an expert programmer to be a successful data scientist, but learning more about programming pays off because becoming a better programmer allows you to automate common tasks and solve new problems with greater ease.

You'll use these tools in every data science project, but they're not enough for most projects. There's a rough 80-20 rule at play; you can tackle about 80% of every project using the tools you'll learn in this book, but you'll need other tools to tackle the remaining 20%. Throughout this book, we'll point you to resources where you can learn more.

1.2 How this book is organized

The previous description of the tools of data science is organized roughly according to the order in which you use them in an analysis (although, of course, you'll iterate through them multiple times). In our experience, however, learning data ingest and tidy first is sub-optimal because 80% of the time, it's routine and boring, and the other 20% of the time, it's weird and frustrating. That's a bad place to start learning a new subject! Instead, we'll start with visualization and transformation of data that's already been imported and tidied. That way, when you ingest and tidy your own data, your motivation will stay high because you know the pain is worth the effort.

Within each chapter, we try and adhere to a similar pattern: start with some motivating examples so you can see the bigger picture and then dive into the details. Each section of the book is paired with exercises to help you practice what you've learned. Although it can be tempting to skip the exercises, there's no better way to learn than practicing on real problems.

1.3 What you won't learn

There are several important topics that this book doesn't cover. We believe it's important to stay ruthlessly focused on the essentials so you can get up and running as quickly as possible. That means this book can't cover every important topic.

1.3.1 Modeling

To learn more about modeling, we highly recommend [Tidy Modeling with R](#) by our colleagues Max Kuhn and Julia Silge. This book will teach you the `tidymodels` family of packages, which, as you might guess from the name, share many conventions with the `tidyverse` packages we use in this book.

1.3.2 Big data

This book proudly focuses on small, in-memory datasets. This is the right place to start because you can't tackle big data unless you have experience with small data. The tools you learn in this book will easily handle hundreds of megabytes of data, and with a bit of care, you can typically use them to work with 1-2 Gb of data. If you're routinely working with larger data (10-100 Gb, say), you should learn more about [`data.table`](#). This book doesn't teach `data.table` because it has a very concise interface that offers fewer linguistic cues, which makes it harder

to learn. However, the performance payoff is well worth the effort required to learn it if you’re working with large data.

If your data is bigger than this, carefully consider whether your big data problem is actually a small data problem in disguise. While the complete data set might be big, often, the data needed to answer a specific question is small. You might be able to find a subset, subsample, or summary that fits in memory and still allows you to answer the question that you’re interested in. The challenge here is finding the right small data, which often requires a lot of iteration.

Another possibility is that your big data problem is actually a large number of small data problems in disguise. Each individual problem might fit in memory, but you have millions of them. For example, you might want to fit a model to each person in your dataset. This would be trivial if you had just 10 or 100 people; instead, you have a million. Fortunately, each problem is independent of the others (a setup that is sometimes called embarrassingly parallel), so you just need a system (like [Hadoop](#) or [Spark](#)) that allows you to send different datasets to different computers for processing. Once you’ve figured out how to answer your question for a single subset using the tools described in this book, you can learn new tools like **sparklyr** to solve it for the full dataset.

1.3.3 Python, Julia, and friends

In this book, you won’t learn anything about Python, Julia, or any other programming language useful for data science. This isn’t because we think these tools are bad. They’re not! And in practice, most data science teams use a mix of languages, often at least R and Python.

However, we strongly believe that it’s best to master one tool at a time. You will get better faster if you dive deep rather than spreading yourself thinly over many topics. This doesn’t mean you should only know one

thing, just that you'll generally learn faster if you stick to one thing at a time. You should strive to learn new things throughout your career, but make sure your understanding is solid before you move on to the next exciting thing.

We think R is a great place to start your data science journey because it is an environment designed from the ground up to support data science. R is not just a programming language; it is also an interactive environment for doing data science. To support interaction, R is a much more flexible language than many of its peers. This flexibility has its downsides, but the big upside is how easy it is to evolve tailored grammars for specific parts of the data science process. These mini languages help you think about problems as a data scientist while supporting fluent interaction between your brain and the computer.

1.4 Prerequisites

We've made a few assumptions about what you already know to get the most out of this book. You should be generally numerically literate, and it's helpful if you have some programming experience already. If you've never programmed before, you might find [Hands on Programming with R](#) by Garrett to be a valuable adjunct to this book.

You need four things to run the code in this book: R, RStudio, a collection of R packages called the **tidyverse**, and a handful of other packages. Packages are the fundamental units of reproducible R code. They include reusable functions, documentation that describes how to use them, and sample data.

1.4.1 R

To download R, go to CRAN, the **comprehensive R archive network**. CRAN is composed of a set of mirror servers distributed around the

world and is used to distribute R and R packages. Don't pick a mirror close to you; instead, use the cloud mirror, <https://cloud.r-project.org>, which automatically figures it out for you.

A new major version of R comes out once a year, and there are 2-3 minor releases each year. It's a good idea to update regularly. Upgrading can be a bit of a hassle, especially for major versions requiring you to re-install all your packages, but putting it off only makes it worse. You'll need at least R 4.1.0 for this book.

1.4.2 RStudio

RStudio is an integrated development environment, or IDE, for R programming. Download and install it from <https://posit.co/download/rstudio-desktop/>. RStudio is updated a couple of times a year. When a new version is available, RStudio will let you know. It's a good idea to upgrade regularly to take advantage of the latest and greatest features. For this book, make sure you have at least RStudio 2022.02.0.

When you start RStudio, [Figure 1.2](#), you'll see two key regions in the interface: the console pane and the output pane. For now, all you need to know is that you type the R code in the console pane and press enter to run it. You'll learn more as we go along!

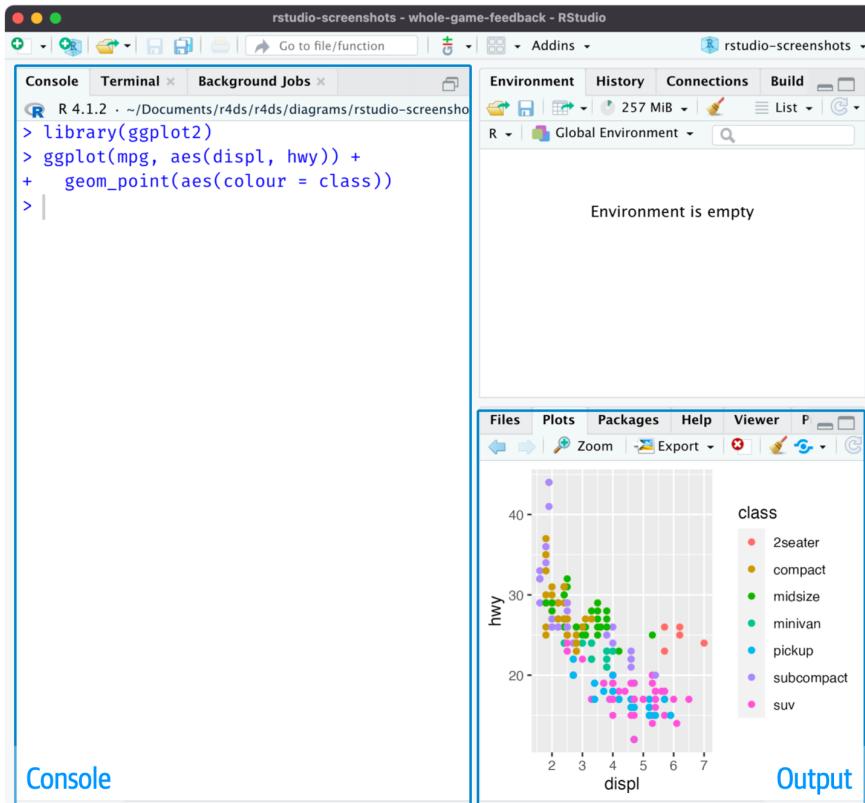

Figure 1.2: The RStudio IDE has two key regions: type R code in the console pane on the left, and look for plots in the output pane on the right.

1.4.3 The tidyverse

You'll also need to install some R packages. An R **package** is a collection of functions, data, and documentation that extends the capabilities of base R. Using packages is key to the successful use of R. The majority of the packages that you will learn in this book are part of the so-called **tidyverse**. All packages in the tidyverse share a common philosophy of data and R programming and are designed to work together naturally.

You can install the complete tidyverse with a single line of code:

```
install.packages("tidyverse")
```

On your computer, type that line of code in the console, and then press enter to run it. R will download the packages from CRAN and install them on your computer. If you have problems installing, make sure that you are connected to the internet and that <https://cloud.r-project.org/> isn't blocked by your firewall or proxy.

You will not be able to use the functions, objects, or help files in a package until you load it with `library()`. Once you have installed a package, you can load it using the `library()` function:

```
library(tidyverse)
#> — Attaching packages —
#> ✓ ggplot2 3.4.0           ✓ purrr   1.0.1.9000
#> ✓ tibble   3.1.8           ✓ dplyr    1.0.99.9000
#> ✓ tidyr    1.2.1.9001      ✓ stringr 1.5.0
#> ✓ readr    2.1.3           ✓forcats 0.5.2
#> — Conflicts —
#> ✘ dplyr::filter() masks stats::filter()
#> ✘ dplyr::lag()   masks stats::lag()
```

This tells you that tidyverse loads eight packages: ggplot2, tibble, tidyR, readr, purrr, dplyr, stringr, andforcats. These are considered the **core** of the tidyverse because you'll use them in almost every analysis.

Packages in the tidyverse change fairly frequently. You can check whether updates are available and optionally install them by running `tidyverse_update()`.

1.4.4 Other packages

There are many other excellent packages that are not part of the tidyverse because they solve problems in a different domain or are designed with a different set of underlying principles. This doesn't make them better or worse, just different. In other words, the complement to the tidyverse is not the messyverse but many other universes of interrelated packages. As you tackle more data science projects with R, you'll learn new packages and new ways of thinking about data.

In this book, we'll use five data packages from outside the tidyverse:

```
install.packages(c("gapminder", "Lahman", "nycflights13"))
```

These packages provide data on world development, baseball, airline flights, and body measurements of penguins that we'll use to illustrate key data science ideas, while the final one helps generate random data sets.

1.5 Running R code

The previous section showed you several examples of running R code. The code in the book looks like this:

```
1 + 2  
#> [1] 3
```

If you run the same code in your local console, it will look like this:

```
> 1 + 2  
[1] 3
```

There are two main differences. In your console, you type after the `>`, called the **prompt**; we don't show the prompt in the book. In the book, the output is commented out with `#>`; in your console, it appears directly after your code. These two differences mean that if you're working with an electronic version of the book, you can easily copy code out of the book and into the console.

Throughout the book, we use a consistent set of conventions to refer to code:

- Functions are displayed in a code font and followed by parentheses, like `sum()` or `mean()`.
- Other R objects (such as data or function arguments) are in a code font, without parentheses, like `flights` or `x`.
- Sometimes, to make it clear which package an object comes from, we'll use the package name followed by two colons, like `dplyr::mutate()` or `nycflights13::flights`. This is also valid R code.

1.6 Acknowledgments

This book isn't just the product of Hadley, Mine, and Garrett but is the result of many conversations (in person and online) that we've had with many people in the R community. There are a few people we'd like to thank in particular because they have spent many hours answering our questions and helping us to better think about data science:

- Jenny Bryan and Lionel Henry for many helpful discussions around working with lists and list-columns.
- The three chapters on workflow were adapted (with permission) from https://stat545.com/block002_hello-r-workspace-wd-

[project.html](#) by Jenny Bryan.

- Yihui Xie for his work on the [bookdown](#) package and for tirelessly responding to my feature requests.
- Bill Behrman for his thoughtful reading of the entire book and for trying it out with his data science class at Stanford.
- The #rstats Twitter community who reviewed all of the draft chapters and provided tons of helpful feedback.

This book was written in the open, and many people contributed pull requests to fix minor problems. Special thanks go to everyone who contributed via GitHub:

A big thank you to all 221 people who contributed specific improvements via GitHub pull requests (in alphabetical order by username): Alex (@ALShum), A. s. R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

Whole game

>

Our goal in this part of the book is to give you a rapid overview of the main tools of data science: **importing**, **tidying**, **transforming**, and **visualizing data**, as shown in [Figure 1](#). We want to show you the “whole game” of data science giving you just enough of all the major pieces so that you can tackle real, if simple, data sets. The later parts of the book, will hit each of these topics in more depth, increasing the range of data science challenges that you can tackle.

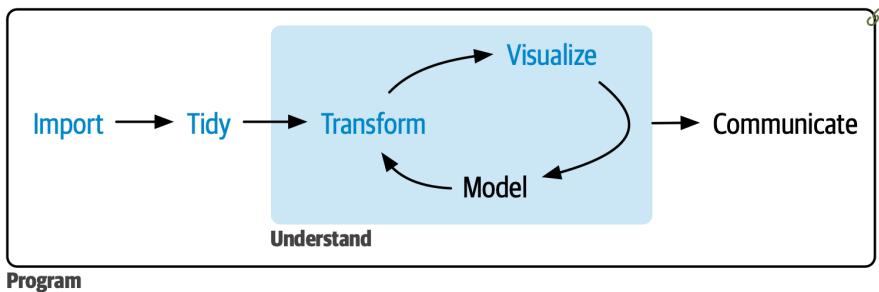

Figure 1: In this section of the book, you’ll learn how to import, tidy, transform, and visualize data.

Five chapters focus on the tools of data science:

- Visualisation is a great place to start with R programming, because the payoff is so clear: you get to make elegant and informative plots that help you understand data. In [Chapter 2](#) you’ll dive into visualization, learning the basic structure of a ggplot2 plot, and powerful techniques for turning data into plots.
- Visualisation alone is typically not enough, so in [Chapter 4](#), you’ll learn the key verbs that allow you to select important variables,

filter out key observations, create new variables, and compute summaries.

- In [Chapter 6](#), you'll learn about tidy data, a consistent way of storing your data that makes transformation, visualization, and modelling easier. You'll learn the underlying principles, and how to get your data into a tidy form.
- Before you can transform and visualize your data, you need to first get your data into R. In [Chapter 8](#) you'll learn the basics of getting `.csv` files into R.

Nestled among these chapters are five other chapters that focus on your R workflow. In [Chapter 3](#), [Chapter 5](#), [Chapter 7](#), and [Chapter 9](#) you'll learn good workflow practices for writing and organizing your R code. These will set you up for success in the long run, as they'll give you the tools to stay organised when you tackle real projects. Finally, [Chapter 10](#) will teach you how to get help to keep learning.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter is largely complete and just needs final proof reading. You can find the complete first edition at <https://r4ds.had.co.nz>.

2.1 Introduction

“The simple graph has brought more information to the data analyst’s mind than any other device.” — John Tukey

R has several systems for making graphs, but ggplot2 is one of the most elegant and most versatile. ggplot2 implements the **grammar of graphics**, a coherent system for describing and building graphs. With ggplot2, you can do more and faster by learning one system and applying it in many places.

This chapter will teach you how to visualize your data using **ggplot2**. We will start by creating a simple scatterplot and use that to introduce aesthetic mappings and geometric objects – the fundamental building blocks of ggplot2. We will then walk you through visualizing distributions of single variables as well as visualizing relationships between two or more variables. We’ll finish off with saving your plots and troubleshooting tips.

2.1.1 Prerequisites

This chapter focuses on `ggplot2`, one of the core packages in the tidyverse. To access the datasets, help pages, and functions used in this chapter, load the tidyverse by running this code:

```
library(tidyverse)
#> — Attaching packages —
#> ✓ ggplot2 3.4.0           ✓ purrr   1.0.1.9000
#> ✓ tibble   3.1.8           ✓ dplyr    1.0.99.9000
#> ✓ tidyr    1.2.1.9001      ✓ stringr 1.5.0
#> ✓ readr    2.1.3           ✓ forcats 0.5.2
#> — Conflicts —
#> ✘ dplyr::filter() masks stats::filter()
#> ✘ dplyr::lag()  masks stats::lag()
```

That one line of code loads the core tidyverse; packages which you will use in almost every data analysis. It also tells you which functions from the tidyverse conflict with functions in base R (or from other packages you might have loaded).

If you run this code and get the error message `there is no package called 'tidyverse'`, you'll need to first install it, then run `library()` once again.

```
install.packages("tidyverse")
library(tidyverse)
```

You only need to install a package once, but you need to reload it every time you start a new session.

In addition to tidyverse, we will also use the **palmerpenguins** package, which includes the `penguins` dataset containing body measurements for penguins on three islands in the Palmer Archipelago.

```
library(palmerpenguins)
```

2.2 First steps

Let's use our first graph to answer a question: Do penguins with longer flippers weigh more or less than penguins with shorter flippers? You probably already have an answer, but try to make your answer precise. What does the relationship between flipper length and body mass look like? Is it positive? Negative? Linear? Nonlinear? Does the relationship vary by the species of the penguin? And how about by the island where the penguin lives.

2.2.1 The `penguins` data frame

You can test your answer with the `penguins` **data frame** found in `palmerpenguins` (a.k.a. `palmerpenguins::penguins`). A data frame is a rectangular collection of variables (in the columns) and observations (in the rows). `penguins` contains 344 observations collected and made available by Dr. Kristen Gorman and the Palmer Station, Antarctica LTER¹.

```
penguins
#> # A tibble: 344 × 8
#>   species     island   bill_length_mm bill_depth_mm flipper_length_mm
#>   <fct>      <fct>           <dbl>            <dbl>             <
#> 1 Adelie    Torgersen        39.1            18.7              18.7
#> 2 Adelie    Torgersen        39.5            17.4              17.4
#> 3 Adelie    Torgersen        40.3             18                18
#> 4 Adelie    Torgersen         NA               NA                NA
#> 5 Adelie    Torgersen        36.7            19.3              19.3
#> 6 Adelie    Torgersen        39.3            20.6              20.6
```

```
#> # ... with 338 more rows, and abbreviated variable name  
#> #   ^body_mass_g
```

This data frame contains 8 columns. For an alternative view, where you can see all variables and the first few observations of each variable, use `glimpse()`. Or, if you're in RStudio, run `View(penguins)` to open an interactive data viewer.

```
glimpse(penguins)  
#> Rows: 344  
#> Columns: 8  
#> $ species          <fct> Adelie, Adelie, Adelie, Ade  
#> $ island            <fct> Torgersen, Torgersen, Torge  
#> $ bill_length_mm    <dbl> 39.1, 39.5, 40.3, NA, 36.7,  
#> $ bill_depth_mm     <dbl> 18.7, 17.4, 18.0, NA, 19.3,  
#> $ flipper_length_mm <int> 181, 186, 195, NA, 193, 190  
#> $ body_mass_g       <int> 3750, 3800, 3250, NA, 3450,  
#> $ sex                <fct> male, female, female, NA, f  
#> $ year              <int> 2007, 2007, 2007, 2007, 200
```

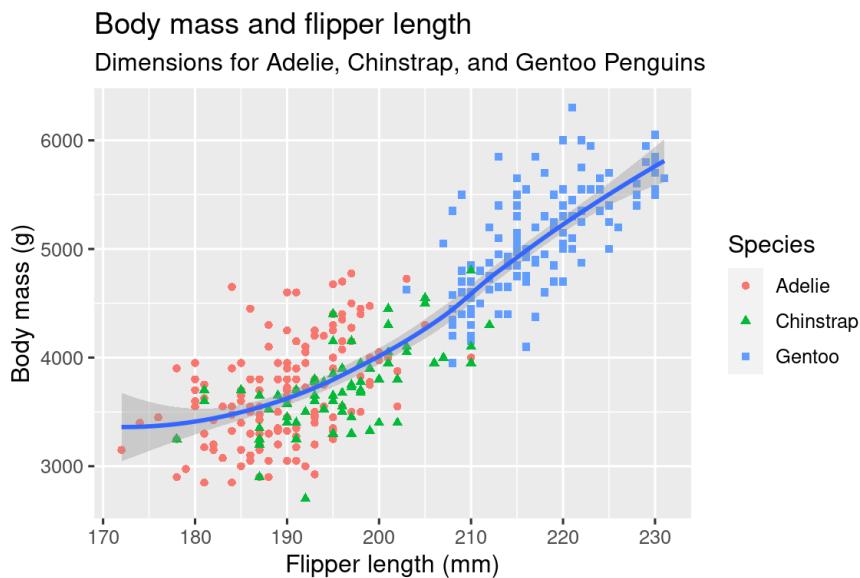

Among the variables in `penguins` are:

1. `species`: a penguin's species (Adelie, Chinstrap, or Gentoo).
2. `flipper_length_mm`: length of a penguin's flipper, in millimeters.
3. `body_mass_g`: body mass of a penguin, in grams.

To learn more about `penguins`, open its help page by running `?penguins`.

2.2.2 Ultimate goal

Our ultimate goal in this chapter is to recreate the following visualization displaying the relationship between flipper lengths and body masses of these penguins, taking into consideration the species of the penguin.

2.2.3 Creating a ggplot

Let's recreate this plot layer-by-layer.

With `ggplot2`, you begin a plot with the function `ggplot()`, defining a plot object that you then add layers to. The first argument of `ggplot()` is the dataset to use in the graph and So `ggplot(data = penguins)` creates an empty graph. This is not a very exciting plot, but you can think of it like an empty canvas you'll paint the remaining layers of your plot onto.

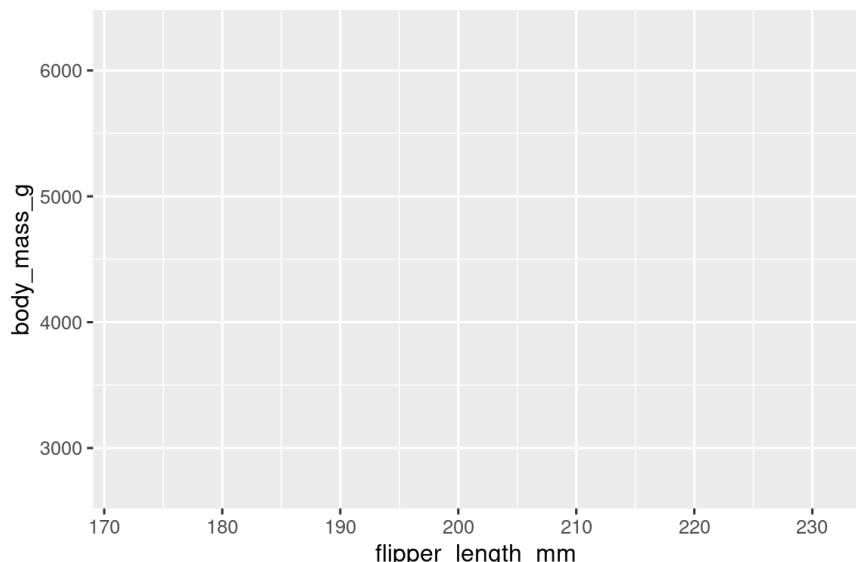

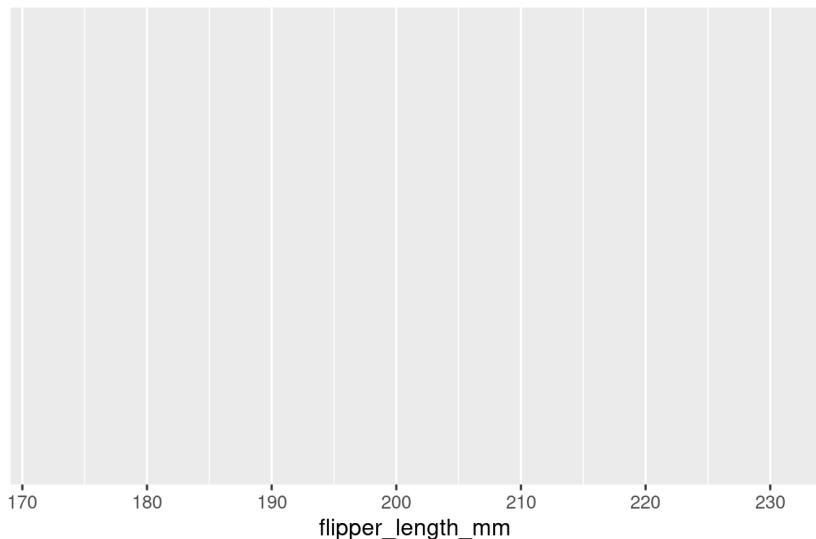

```
ggplot(data = penguins)
```

Next, we need to tell `ggplot()` the variables from this data frame that we want to map to visual properties (**aesthetics**) of the plot. The `mapping` argument of the `ggplot()` function defines how variables in your dataset are mapped to visual properties of your plot. The `mapping` argument is always paired with the `aes()` function, and the `x` and `y` arguments of `aes()` specify which variables to map to the `x` and `y` axes. For now, we will only map flipper length to the `x` aesthetic and body mass to the `y` aesthetic. `ggplot2` looks for the mapped variables in the `data` argument, in this case, `penguins`.

The following plots show the result of adding these mappings, one at a time.

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm)  
)  
ggplot(  
  data = penguins,
```

```
mapping = aes(x = flipper_length_mm, y = body_mass_g)  
)
```

Our empty canvas now has more structure – it's clear where flipper lengths will be displayed (on the x-axis) and where body masses will be displayed (on the y-axis). But the penguins themselves are not yet on

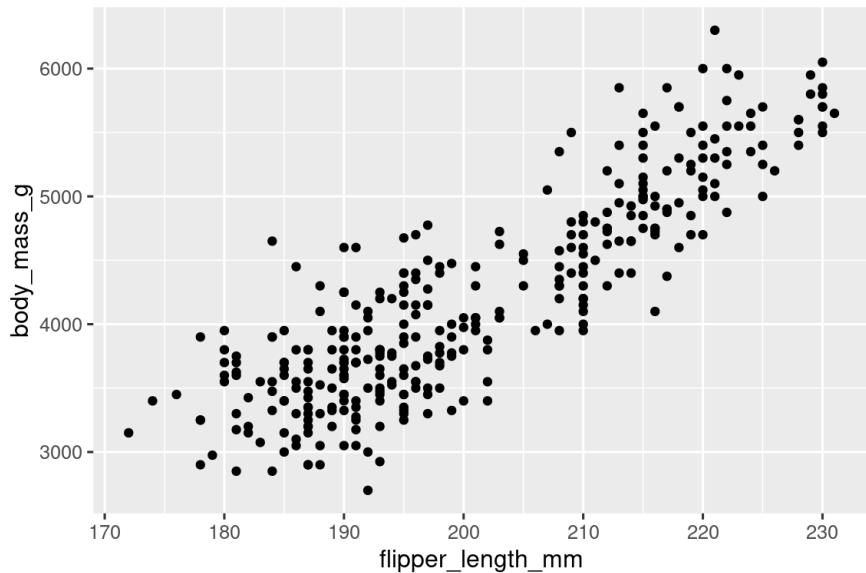

the plot. This is because we have not yet articulated, in our code, how to represent the observations from our data frame on our plot.

To do so, we need to define a **geom**: the geometrical object that a plot uses to represent data. These geometric objects are made available in ggplot2 with functions that start with `geom_`. People often describe plots by the type of geom that the plot uses. For example, bar charts use bar geoms (`geom_bar()`), line charts use line geoms (`geom_line()`), boxplots use boxplot geoms (`geom_boxplot()`), and so on.

Scatterplots break the trend; they use the point geom: `geom_point()`.

The function `geom_point()` adds a layer of points to your plot, which creates a scatterplot. ggplot2 comes with many geom functions that each adds a different type of layer to a plot. You'll learn a whole bunch of geoms throughout the book, particularly in [Chapter 11](#).

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass_g)  
) +  
  geom_point()  
#> Warning: Removed 2 rows containing missing values (`g
```

Now we have something that looks like what we might think of as a “scatter plot”. It doesn’t yet match our “ultimate goal” plot, but using this plot we can start answering the question that motivated our exploration: “What does the relationship between flipper length and body mass look like?” The relationship appears to be positive, fairly linear, and moderately strong. Penguins with longer flippers are generally larger in terms of their body mass.

Before we add more layers to this plot, let’s pause for a moment and review the warning message we got:

Removed 2 rows containing missing values (`geom_point()`).

We’re seeing this message because there are two penguins in our dataset with missing body mass and flipper length values and ggplot2 has no way of representing them on the plot. You don’t need to worry about understanding the following code yet (you will learn about it in

[Chapter 4](#)), but it's one way of identifying the observations with `NA`s for either body mass or flipper length.

```
penguins |>
  select(species, flipper_length_mm, body_mass_g) |>
  filter(is.na(body_mass_g) | is.na(flipper_length_mm))
#> # A tibble: 2 × 3
#>   species flipper_length_mm body_mass_g
#>   <fct>          <int>        <int>
#> 1 Adelie            NA           NA
#> 2 Gentoo           NA           NA
```

Like R, ggplot2 subscribes to the philosophy that missing values should never silently go missing. This type of warning is probably one of the most common types of warnings you will see when working with real data – missing values are a very common issue and you'll learn more about them throughout the book, particularly in [Chapter 20](#). For the remaining plots in this chapter we will suppress this warning so it's not printed alongside every single plot we make.

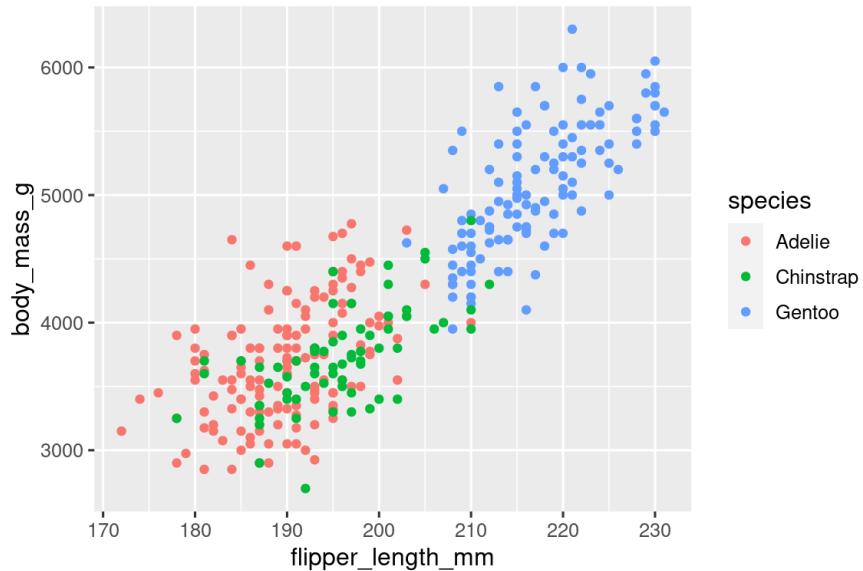

2.2.4 Adding aesthetics and layers

Scatterplots are useful for displaying the relationship between two variables, but it's always a good idea to be skeptical of any apparent relationship between two variables and ask if there may be other variables that explain or change the nature of this apparent relationship. Let's incorporate species into our plot and see if this reveals any additional insights into the apparent relationship between flipper length and body mass. We will do this by representing species with different colored points.

To achieve this, where should `species` go in the `ggplot` call from earlier? If you guessed “in the aesthetic mapping, inside of `aes()`”, you're already getting the hang of creating data visualizations with

ggplot2! And if not, don't worry. Throughout the book you will make many more ggplots and have many more opportunities to check your intuition as you make them.

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass_g,  
) +  
  geom_point()
```

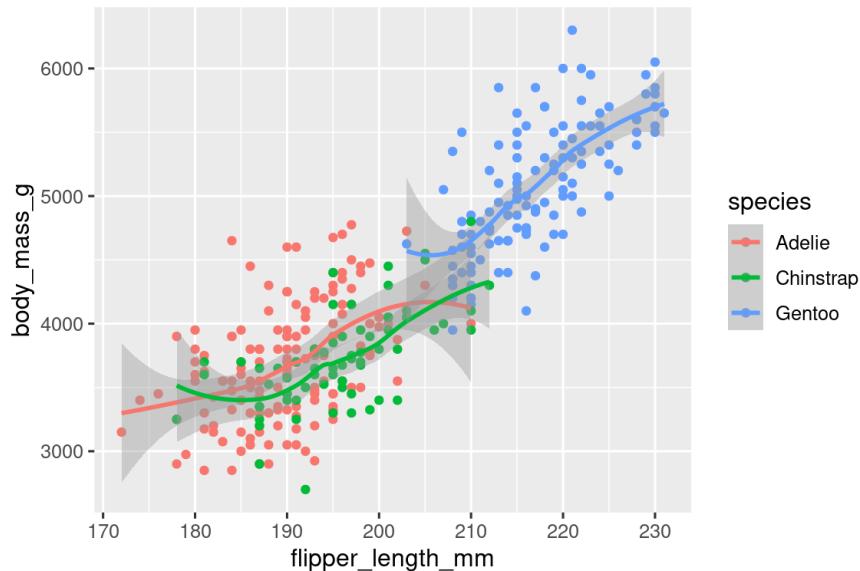

When a variable is mapped to an aesthetic, ggplot2 will automatically assign a unique value of the aesthetic (here a unique color) to each unique level of the variable (each of the three species), a process known as **scaling**. ggplot2 will also add a legend that explains which values correspond to which levels.

Now let's add one more layer: a smooth curve displaying the relationship between body mass and flipper length. Before you proceed,

refer back to the code above, and think about how we can add this to our existing plot.

Since this is a new geometric object representing our data, we will add a new geom: `geom_smooth()`.

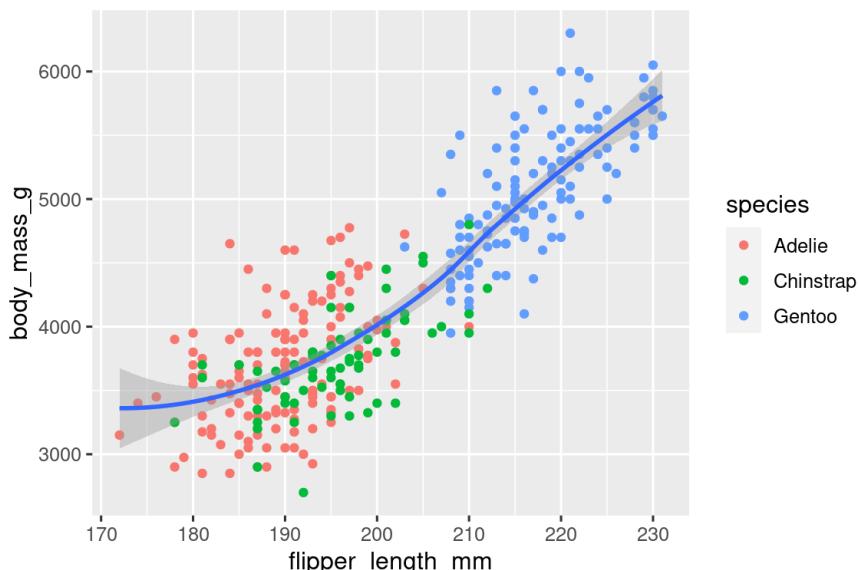

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass_g,  
) +  
  geom_point() +  
  geom_smooth()
```

We have successfully added smooth curves, but this plot doesn't look like the plot from [Section 2.2.2](#), which only has one curve for the entire dataset as opposed to separate curves for each of the penguin species.

When aesthetic mappings are defined in `ggplot()`, at the *global* level, they're inherited by each of the subsequent geom layers of the plot. However, each geom function in ggplot2 can also take a `mapping` argument, which allows for aesthetic mappings at the *local* level. Since we want points to be colored based on species but don't want the smooth curves to be separated out for them, we should specify `color = species` for `geom_point()` only.

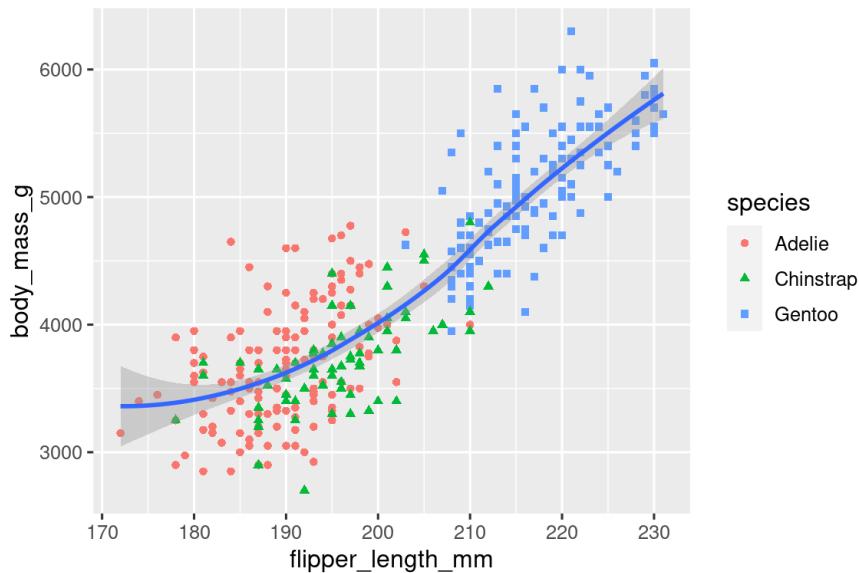

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass_g)  
) +  
  geom_point(mapping = aes(color = species)) +  
  geom_smooth()
```

Voila! We have something that looks very much like our ultimate goal, though it's not yet perfect. We still need to use different shapes for each species of penguins and improve labels.

It's generally not a good idea to represent information using only colors on a plot, as people perceive colors differently due to color blindness or other color vision differences. Therefore, in addition to color, we can also map `species` to the `shape` aesthetic.

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass_g)  
) +  
  geom_point(mapping = aes(color = species, shape = specie  
  geom_smooth()
```

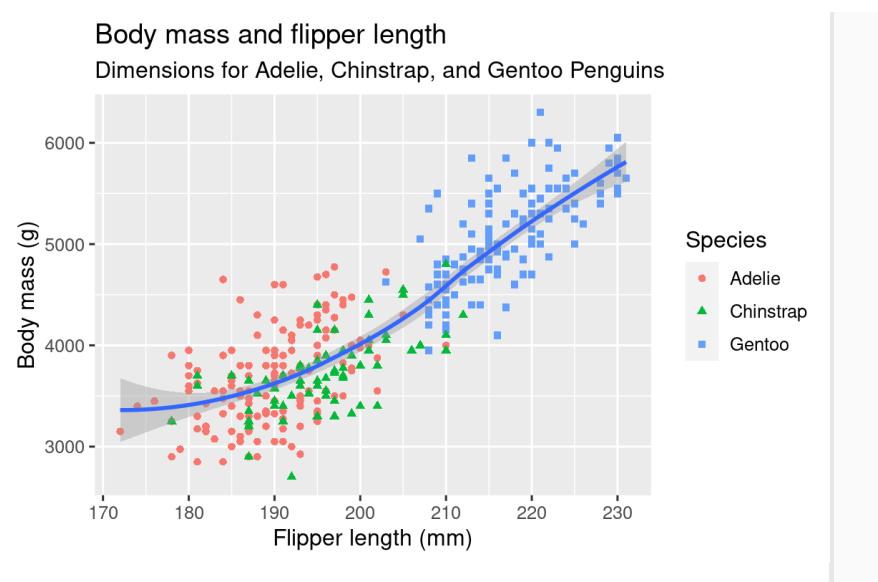

Note that the legend is automatically updated to reflect the different shapes of the points as well.

And finally, we can improve the labels of our plot using the `labs()` function in a new layer. Some of the arguments to `labs()` might be self explanatory: `title` adds a title and `subtitle` adds a subtitle to the

plot. Other arguments match the aesthetic mappings, `x` is the x-axis label, `y` is the y-axis label, and `color` and `shape` define the label for the legend.

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass_g)  
) +  
  geom_point(aes(color = species, shape = species)) +  
  geom_smooth() +  
  labs(  
    title = "Body mass and flipper length",  
    subtitle = "Dimensions for Adelie, Chinstrap, and Gentoo Penguins",  
    x = "Flipper length (mm)",  
    y = "Body mass (g)",  
    color = "Species",  
    shape = "Species"  
)
```

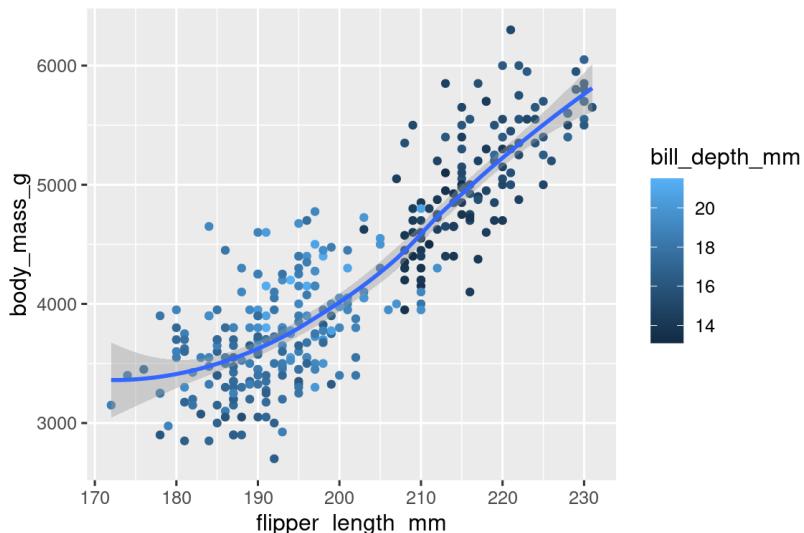

We finally have a plot that perfectly matches our “ultimate goal”!

2.2.5 Exercises

1. How many rows are in `penguins`? How many columns?
2. What does the `bill_depth_mm` variable in the `penguins` data frame describe? Read the help for `?penguins` to find out.
3. Make a scatterplot of `bill_depth_mm` vs. `bill_length_mm`. Describe the relationship between these two variables.
4. What happens if you make a scatterplot of `species` vs `bill_depth_mm`? Why is the plot not useful?
5. Why does the following give an error and how would you fix it?

```
ggplot(data = penguins) +  
  geom_point()
```

6. What does the `na.rm` argument do in `geom_point()`? What is the default value of the argument? Create a scatterplot where you successfully use this argument set to `TRUE`.
7. Add the following caption to the plot you made in the previous exercise: “Data come from the `palmerpenguins` package.” Hint: Take a look at the documentation for `labs()`.
8. Recreate the following visualization. What aesthetic should `bill_depth_mm` be mapped to? And should it be mapped at the global level or at the geom level?

9. Run this code in your head and predict what the output will look like. Then, run the code in R and check your predictions.

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass  
) +  
  geom_point() +  
  geom_smooth(se = FALSE)
```

10. Will these two graphs look different? Why/why not?

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass  
) +  
  geom_point() +  
  geom_smooth()
```

```
ggplot() +  
  geom_point(  
    data = penguins,  
    mapping = aes(x = flipper_length_mm, y = body_mass_g  
) +  
  geom_smooth(  
    data = penguins,  
    mapping = aes(x = flipper_length_mm, y = body_mass_g  
)
```

2.3 ggplot2 calls

As we move on from these introductory sections, we'll transition to a more concise expression of ggplot2 code. So far we've been very explicit, which is helpful when you are learning:

```
ggplot(  
  data = penguins,  
  mapping = aes(x = flipper_length_mm, y = body_mass_g)  
) +  
  geom_point()
```

Typically, the first one or two arguments to a function are so important that you should know them by heart. The first two arguments to `ggplot()` are `data` and `mapping`, in the remainder of the book, we won't supply those names. That saves typing, and, by reducing the amount of boilerplate, makes it easier to see what's different between plots. That's a really important programming concern that we'll come back to in [Chapter 27](#).

Rewriting the previous plot more concisely yields:

```
ggplot(penguins, aes(x = flipper_length_mm, y = body_mass_g)) +  
  geom_point()
```

In the future, you'll also learn about the pipe which will allow you to create that plot with:

```
penguins |>  
  ggplot(aes(x = flipper_length_mm, y = body_mass_g)) +  
  geom_point()
```

This is the most common syntax you'll see in the wild.

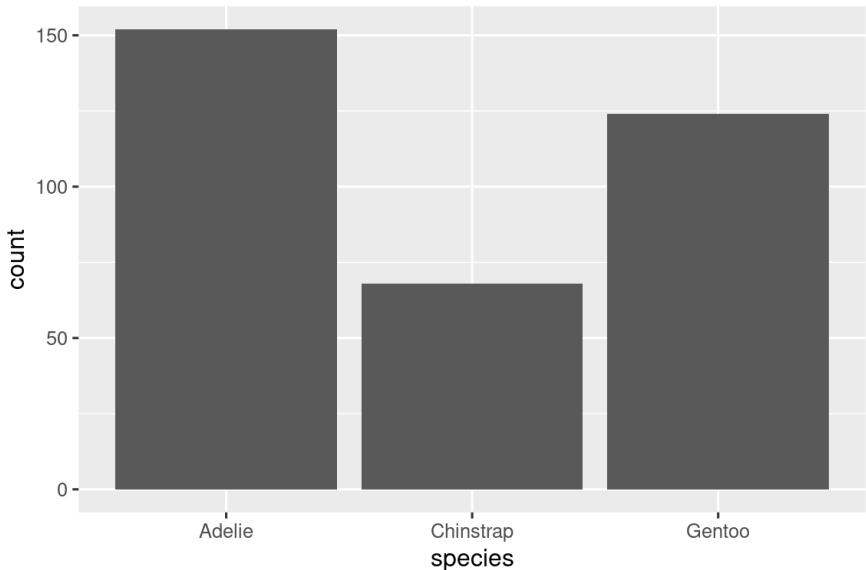

2.4 Visualizing distributions

How you visualize the distribution of a variable depends on the type of variable: categorical or numerical.

2.4.1 A categorical variable

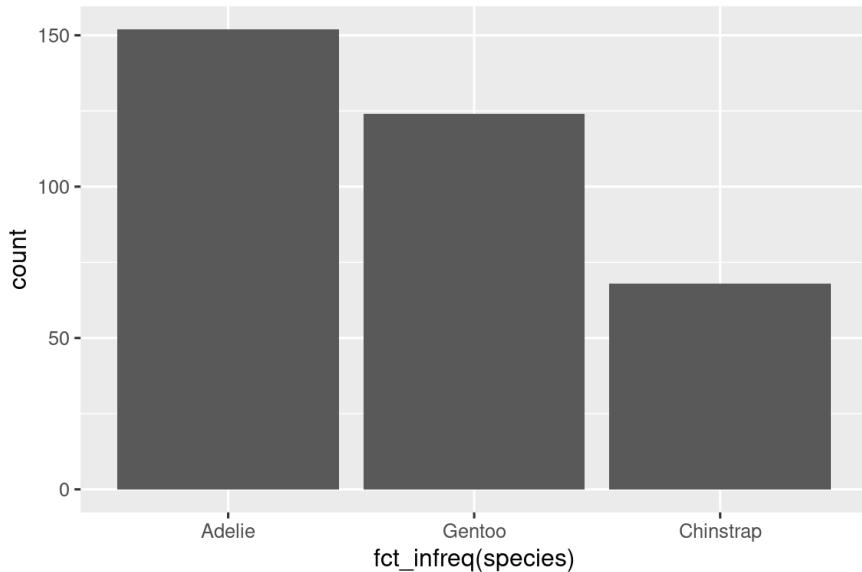

A variable is **categorical** if it can only take one of a small set of values. To examine the distribution of a categorical variable, you can use a bar chart. The height of the bars displays how many observations occurred with each `x` value.

```
ggplot(penguins, aes(x = species)) +  
  geom_bar()
```

In bar plots of categorical variables with non-ordered levels, like the `penguin species` above, it's often preferable to reorder the bars based on their frequencies. Doing so requires transforming the variable to a factor (how R handles categorical data) and then reordering the levels of that factor.

```
ggplot(penguins, aes(x = fct_infreq(species))) +  
  geom_bar()
```

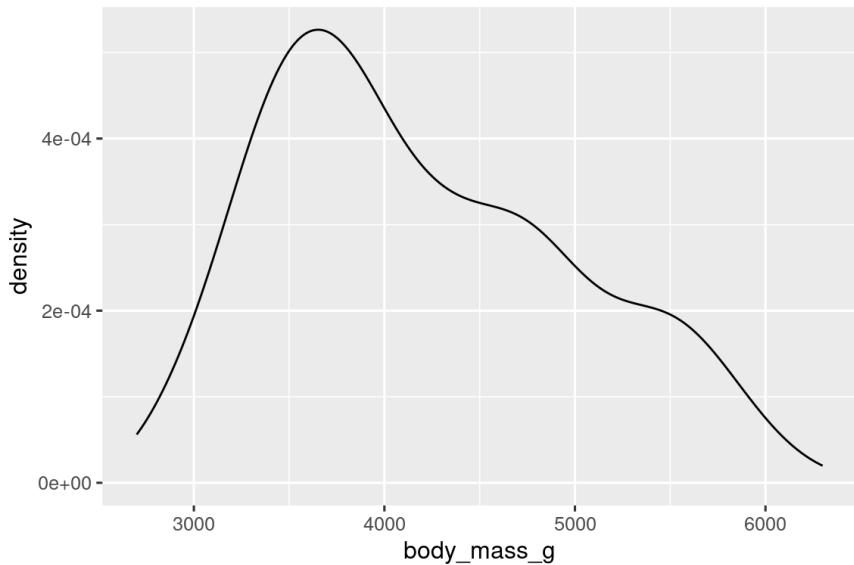

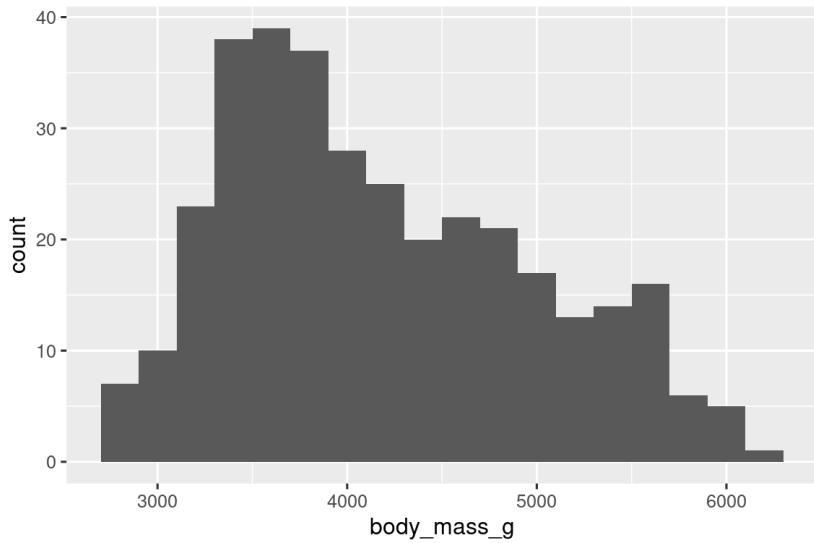

You will learn more about factors and functions for dealing with factors (like `fct_infreq()` shown above) in [Chapter 18](#).

2.4.2 A numerical variable

A variable is **numerical** if it can take any of an infinite set of ordered values. Numbers and date-times are two examples of continuous variables. To visualize the distribution of a continuous variable, you can use a histogram or a density plot.

```
ggplot(penguins, aes(x = body_mass_g)) +  
  geom_histogram(binwidth = 200)  
ggplot(penguins, aes(x = body_mass_g)) +  
  geom_density()
```

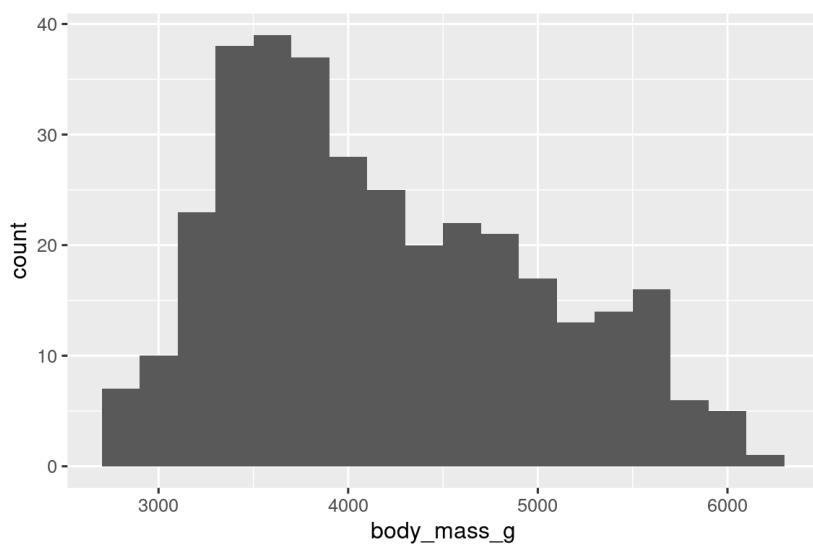

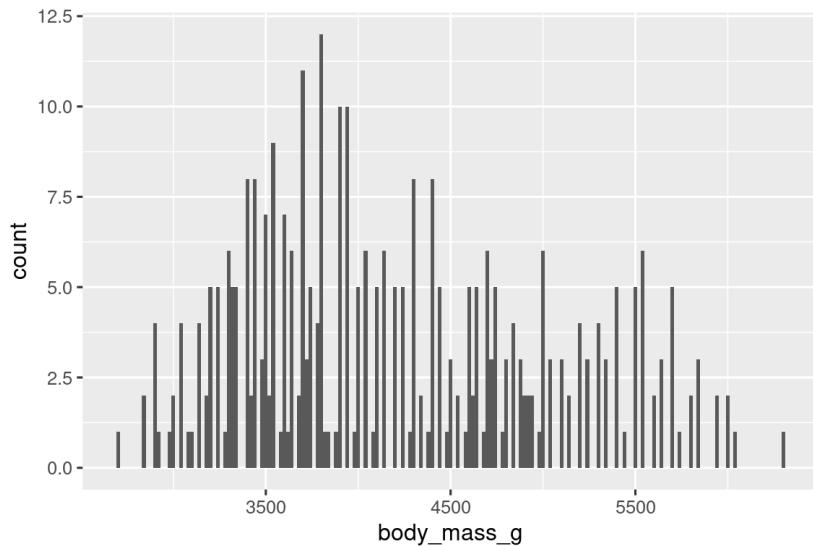

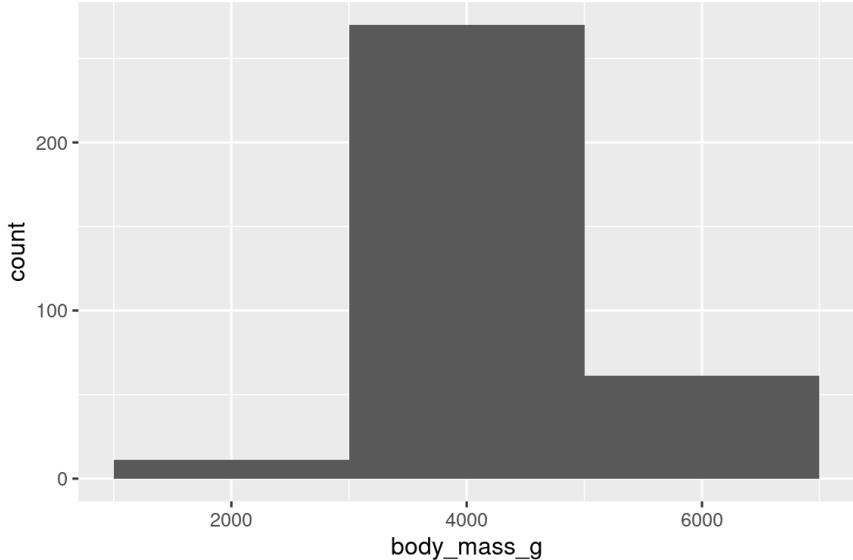

A histogram divides the x-axis into equally spaced bins and then uses the height of a bar to display the number of observations that fall in each bin. In the graph above, the tallest bar shows that 39 observations have a `body_mass_g` value between 3,500 and 3,700 grams, which are the left and right edges of the bar.

```
penguins |>
  count(cut_width(body_mass_g, 200))
#> # A tibble: 19 × 2
#>   `cut_width(body_mass_g, 200)`     n
#>   <fct>                      <int>
#> 1 [2.7e+03,2.9e+03]                7
#> 2 (2.9e+03,3.1e+03]               10
#> 3 (3.1e+03,3.3e+03]              23
#> 4 (3.3e+03,3.5e+03]              38
#> 5 (3.5e+03,3.7e+03]              39
#> 6 (3.7e+03,3.9e+03]              37
#> # ... with 13 more rows
```

You can set the width of the intervals in a histogram with the binwidth argument, which is measured in the units of the `x` variable. You should always explore a variety of binwidths when working with histograms, as different binwidths can reveal different patterns. In the plots below a binwidth of 20 is too narrow, resulting in too many bars, making it difficult to determine the shape of the distribution. Similarly, a binwidth of 2,000 is too high, resulting in all data being binned into only three bars, and also making it difficult to determine the shape of the distribution.

```
ggplot(penguins, aes(x = body_mass_g)) +
  geom_histogram(binwidth = 20)
ggplot(penguins, aes(x = body_mass_g)) +
  geom_histogram(binwidth = 200)
ggplot(penguins, aes(x = body_mass_g)) +
  geom_histogram(binwidth = 2000)
```

2.4.3 Exercises

1. Make a bar plot of `species` of penguins , where you assign `species` to the `y` aesthetic. How is this plot different?
2. How are the following two plots different? Which aesthetic, `color` or `fill`, is more useful for changing the color of bars?

```
ggplot(penguins, aes(x = species)) +  
  geom_bar(color = "red")
```

```
ggplot(penguins, aes(x = species)) +  
  geom_bar(fill = "red")
```

3. What does the `bins` argument in `geom_histogram()` do?
4. Make a histogram of the `carat` variable in the `diamonds` dataset. Experiment with different binwidths. What binwidth reveals the most interesting patterns?

2.5 Visualizing relationships

To visualize a relationship we need to have at least two variables mapped to aesthetics of a plot. In the following sections you will learn about commonly used plots for visualizing relationships between two or more variables and the geoms used for creating them.

2.5.1 A numerical and a categorical variable

To visualize the relationship between a numerical and a categorical variable we can use side-by-side box plots. A **boxplot** is a type of visual shorthand for a distribution of values that is popular among statisticians. As shown in [Figure 2.1](#), each boxplot consists of:

- A box that stretches from the 25th percentile of the distribution to the 75th percentile, a distance known as the interquartile range (IQR). In the middle of the box is a line that displays the median, i.e. 50th percentile, of the distribution. These three lines give you a sense of the spread of the distribution and whether or not the distribution is symmetric about the median or skewed to one side.
- Visual points that display observations that fall more than 1.5 times the IQR from either edge of the box. These outlying points are unusual so are plotted individually.
- A line (or whisker) that extends from each end of the box and goes to the farthest non-outlier point in the distribution.

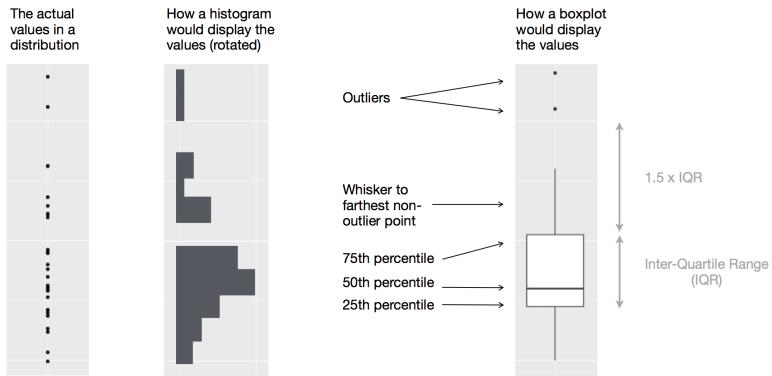

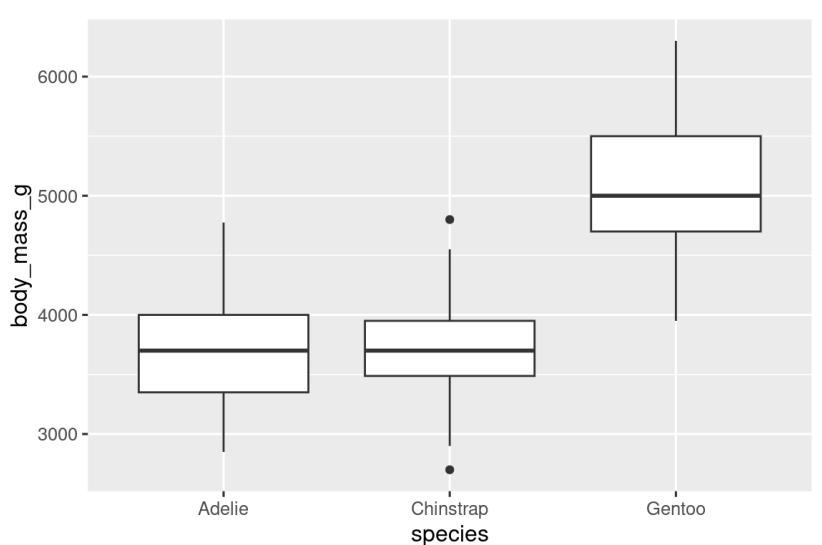

Figure 2.1: Diagram depicting how a boxplot is created.

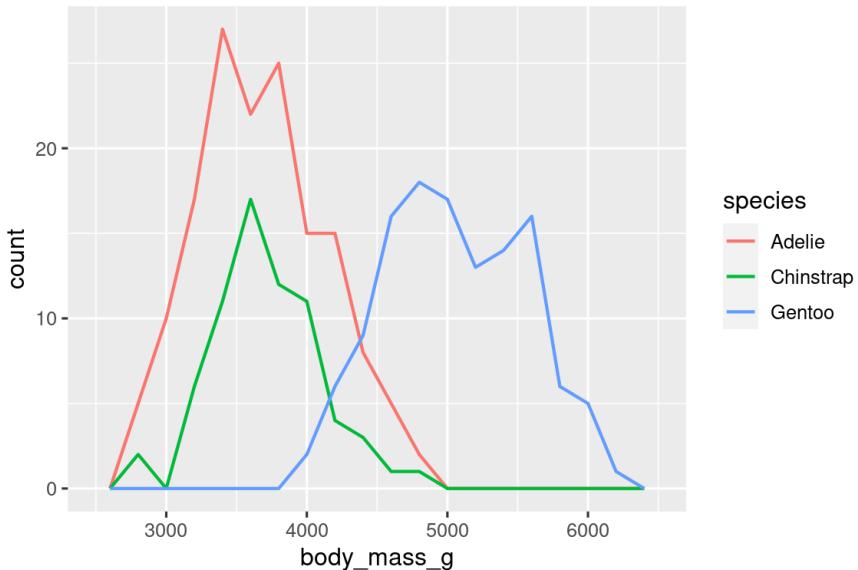

Let's take a look at the distribution of body mass by species using `geom_boxplot()`:

```
ggplot(penguins, aes(x = species, y = body_mass_g)) +
  geom_boxplot()
```

Alternatively, we can make frequency polygons with `geom_freqpoly()`. `geom_freqpoly()` performs the same calculation as `geom_histogram()`, but instead of displaying the counts with bars, it uses lines instead. It's much easier to understand overlapping lines than bars of `geom_histogram()`. There are a few challenges with this type of plot, which we will come back to in [Section 12.5.1](#) on exploring the covariation between a categorical and a numerical variable.

```
ggplot(penguins, aes(x = body_mass_g, color = species))  
  geom_freqpoly(binwidth = 200, linewidth = 0.75)
```

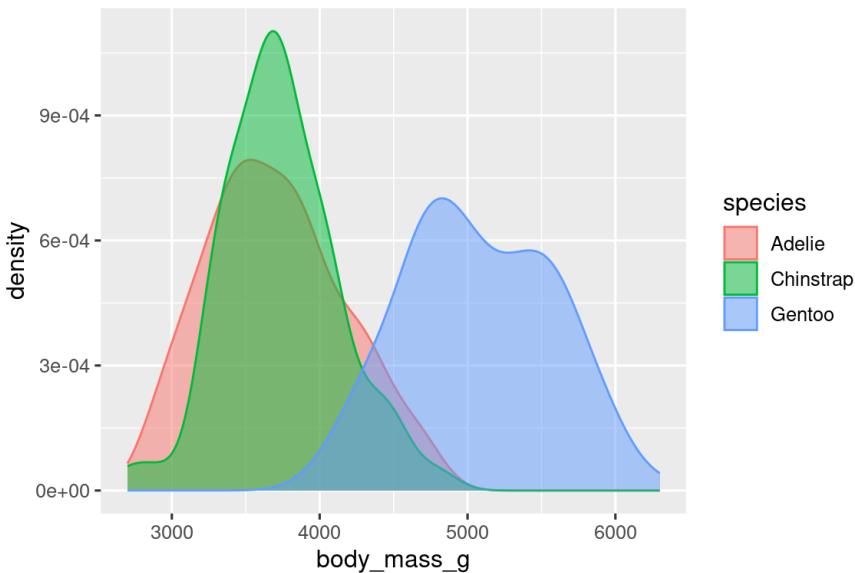

We've also customized the thickness of the lines using the `linewidth` argument in order to make them stand out a bit more against the background.

We can also use overlaid density plots, with `species` mapped to both `color` and `fill` aesthetics and using the `alpha` aesthetic to add

transparency to the filled density curves. This aesthetic takes values between 0 (completely transparent) and 1 (completely opaque). In the following plot it's set to 0.5.

```
ggplot(penguins, aes(x = body_mass_g, color = species, f  
geom_density(alpha = 0.5)
```

Note the terminology we have used here:

- We *map* variables to aesthetics if we want the visual attribute represented by that aesthetic to vary based on the values of that variable.
- Otherwise, we *set* the value of an aesthetic.

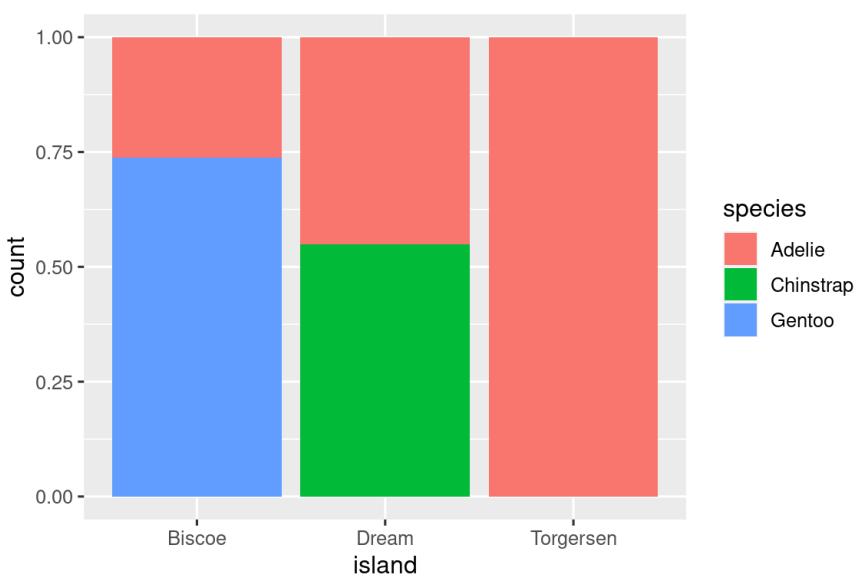

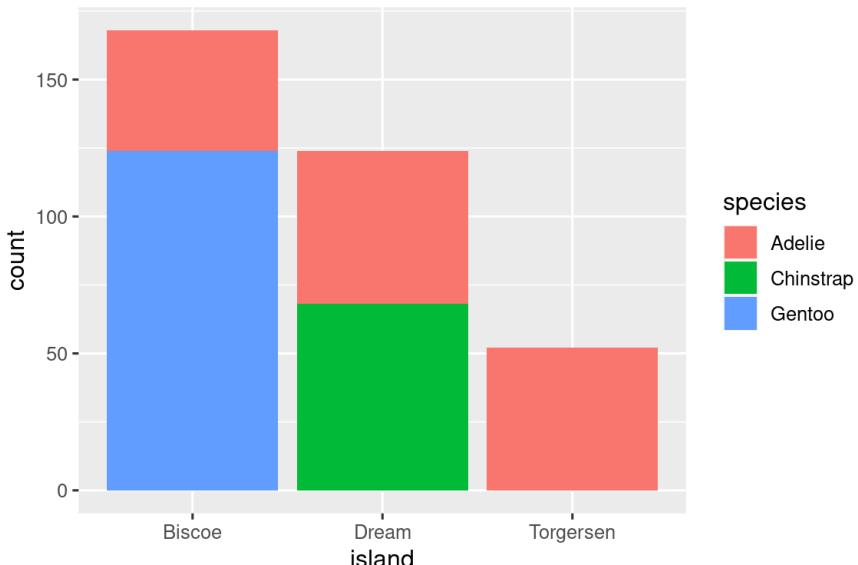

2.5.2 Two categorical variables

We can use segmented bar plots to visualize the distribution between two categorical variables. In creating this bar chart, we map the variable

we want to divide the data into first to the `x` aesthetic and the variable we then further want to divide each group into to the `fill` aesthetic.

Below are two segmented bar plots, both displaying the relationship between `island` and `species`, or specifically, visualizing the distribution of `species` within each island. The plot on the left shows the frequencies of each species of penguins on each island and the plot on the right shows the relative frequencies (proportions) of each species within each island (despite the incorrectly labeled y-axis that says “count”). The relative frequency plot, created by setting `position = "fill"` in the `geom` is more useful for comparing species distributions across islands since it's not affected by the unequal numbers of penguins across the islands. Based on the plot on the left, we can see that Gentoo penguins all live on Biscoe island and make up roughly 75% of the penguins on that island, Chinstrap all live on Dream island and make up roughly 50% of the penguins on that island, and Adelie live on all three islands and make up all of the penguins on Torgersen.

```
ggplot(penguins, aes(x = island, fill = species)) +  
  geom_bar()  
ggplot(penguins, aes(x = island, fill = species)) +  
  geom_bar(position = "fill")
```

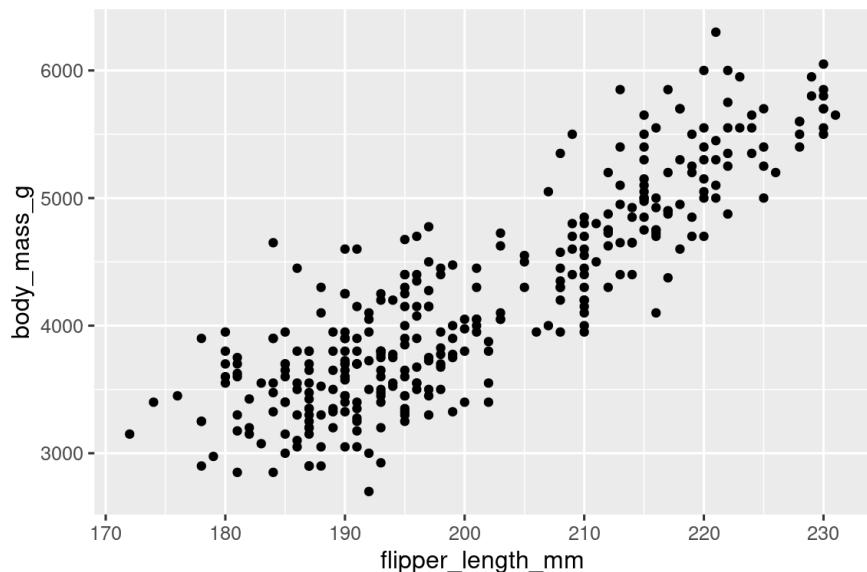

2.5.3 Two numerical variables

So far you've learned about scatterplots (created with `geom_point()`) and smooth curves (created with `geom_smooth()`) for visualizing the

relationship between two numerical variables. A scatterplot is probably the most commonly used plot for visualizing the relationship between two variables.

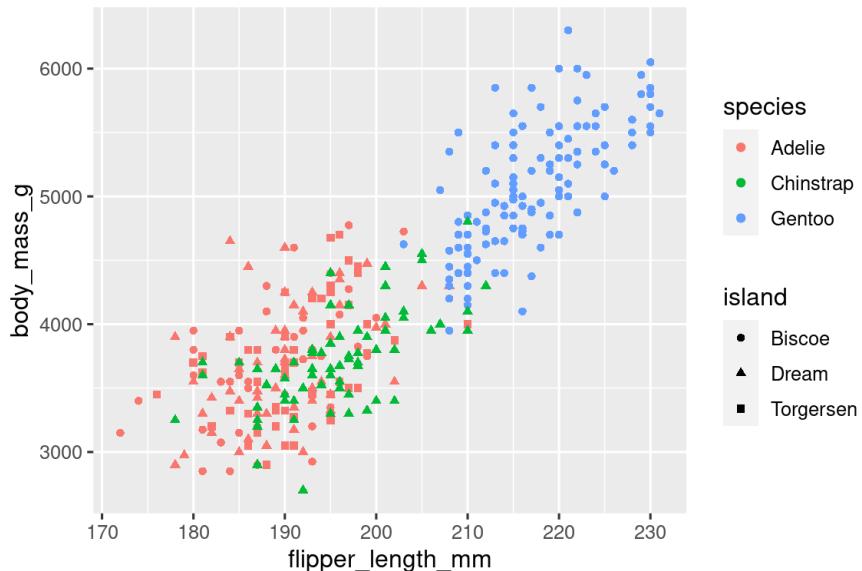

```
ggplot(penguins, aes(x = flipper_length_mm, y = body_mass_g)) +  
  geom_point()
```

2.5.4 Three or more variables

One way to add additional variables to a plot is by mapping them to an aesthetic. For example, in the following scatterplot the colors of points represent species and the shapes of points represent islands.

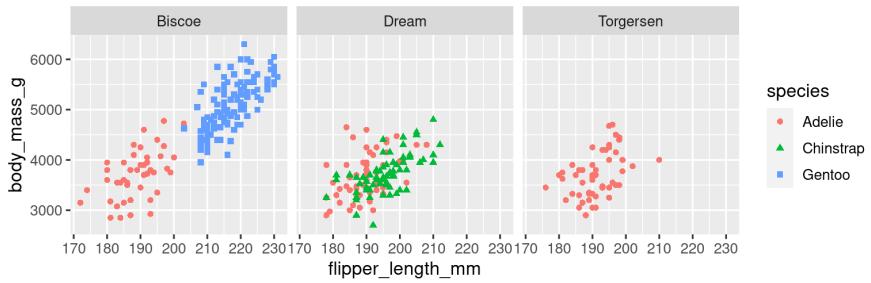

```
ggplot(penguins, aes(x = flipper_length_mm, y = body_mass_g)) +  
  geom_point(aes(color = species, shape = island))
```

However adding too many aesthetic mappings to a plot makes it cluttered and difficult to make sense of. Another way, which is particularly useful for categorical variables, is to split your plot into **facets**, subplots that each display one subset of the data.

To facet your plot by a single variable, use `facet_wrap()`. The first argument of `facet_wrap()` is a formula², which you create with `~` followed by a variable name. The variable that you pass to `facet_wrap()` should be categorical.

```
ggplot(penguins, aes(x = flipper_length_mm, y = body_mass_g)) +  
  geom_point(aes(color = species, shape = species)) +  
  facet_wrap(~island)
```

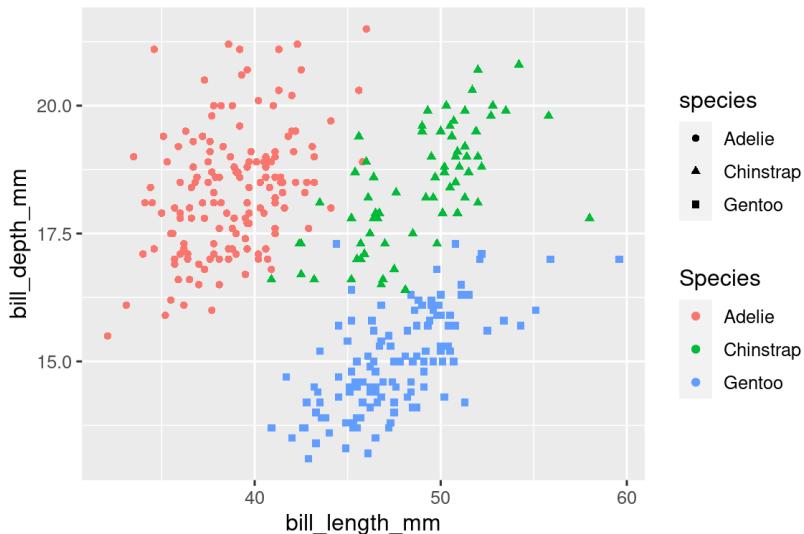

You will learn about many other geoms for visualizing distributions of variables and relationships between them in [Chapter 11](#).

2.5.5 Exercises

1. Which variables in `mpg` are categorical? Which variables are continuous? (Hint: type `?mpg` to read the documentation for the dataset). How can you see this information when you run `mpg`?
2. Make a scatterplot of `hwy` vs. `displ` using the `mpg` data frame. Next, map a third, numerical variable to `color`, then `size`, then both `color` and `size`, then `shape`. How do these aesthetics behave differently for categorical vs. numerical variables?
3. In the scatterplot of `hwy` vs. `displ`, what happens if you map a third variable to `linewidth`?
4. What happens if you map the same variable to multiple aesthetics?
5. Make a scatterplot of `bill_depth_mm` vs. `bill_length_mm` and color the points by `species`. What does adding coloring by species reveal about the relationship between these two variables?
6. Why does the following yield two separate legends? How would you fix it to combine the two legends?

```
ggplot(  
  data = penguins,  
  mapping = aes(  
    x = bill_length_mm, y = bill_depth_mm,  
    color = species, shape = species  
  )  
) +  
  geom_point() +  
  labs(color = "Species")
```

2.6 Saving your plots

Once you've made a plot, you might want to get it out of R by saving it as an image that you can use elsewhere. That's the job of `ggsave()`, which will save the most recent plot to disk:

```
ggplot(penguins, aes(x = flipper_length_mm, y = body_mass_g))  
  geom_point()
```

```
ggsave(filename = "my-plot.png")
```

This will save your plot to your working directory, a concept you'll learn more about in [Chapter 9](#).

If you don't specify the `width` and `height` they will be taken from the dimensions of the current plotting device. For reproducible code, you'll want to specify them. You can learn more about `ggsave()` in the documentation.

Generally, however, we recommend that you assemble your final reports using Quarto, a reproducible authoring system that allows you to interleave your code and your prose and automatically include your plots in your write-ups. You will learn more about Quarto in [Chapter 30](#).

2.6.1 Exercises

1. Run the following lines of code. Which of the two plots is saved as `mpg-plot.png`? Why?

```
ggplot(mpg, aes(x = class)) +  
  geom_bar()  
ggplot(mpg, aes(x = cty, y = hwy)) +  
  geom_point()  
ggsave("mpg-plot.png")
```

2. What do you need to change in the code above to save the plot as a PDF instead of a PNG?

2.7 Common problems

As you start to run R code, you're likely to run into problems. Don't worry — it happens to everyone. We have all been writing R code for

years, but every day we still write code that doesn't work!

Start by carefully comparing the code that you're running to the code in the book. R is extremely picky, and a misplaced character can make all the difference. Make sure that every `(` is matched with a `)` and every `"` is paired with another `"`. Sometimes you'll run the code and nothing happens. Check the left-hand of your console: if it's a `+`, it means that R doesn't think you've typed a complete expression and it's waiting for you to finish it. In this case, it's usually easy to start from scratch again by pressing ESCAPE to abort processing the current command.

One common problem when creating ggplot2 graphics is to put the `+` in the wrong place: it has to come at the end of the line, not the start. In other words, make sure you haven't accidentally written code like this:

```
ggplot(data = mpg)  
+ geom_point(mapping = aes(x = displ, y = hwy))
```

If you're still stuck, try the help. You can get help about any R function by running `?function_name` in the console, or selecting the function name and pressing F1 in RStudio. Don't worry if the help doesn't seem that helpful - instead skip down to the examples and look for code that matches what you're trying to do.

If that doesn't help, carefully read the error message. Sometimes the answer will be buried there! But when you're new to R, even if the answer is in the error message, you might not yet know how to understand it. Another great tool is Google: try googling the error message, as it's likely someone else has had the same problem, and has gotten help online.

2.8 Summary

In this chapter, you've learned the basics of data visualization with ggplot2. We started with the basic idea that underpins ggplot2: a visualization is a mapping from variables in your data to aesthetic properties like position, color, size and shape. You then learned about increasing the complexity and improving the presentation of your plots layer-by-layer. You also learned about commonly used plots for visualizing the distribution of a single variable as well as for visualizing relationships between two or more variables, by leveraging additional aesthetic mappings and/or splitting your plot into small multiples using faceting.

We'll use visualizations again and again throughout this book, introducing new techniques as we need them as well as do a deeper dive into creating visualizations with ggplot2 in [Chapter 11](#) through [Chapter 12](#).

With the basics of visualization under your belt, in the next chapter we're going to switch gears a little and give you some practical workflow advice. We intersperse workflow advice with data science tools throughout this part of the book because it'll help you stay organized as you write increasing amounts of R code.

1. Horst AM, Hill AP, Gorman KB (2020). palmerpenguins: Palmer Archipelago (Antarctica) penguin data. R package version 0.1.0. <https://allisonhorst.github.io/palmerpenguins/>. doi: 10.5281/zenodo.3960218. 
2. Here “formula” is the name of the type of thing created by `~`, not a synonym for “equation”. 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built
with [Quarto](#).

3 Workflow: basics

>

i You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

You now have some experience running R code. We didn't give you many details, but you've obviously figured out the basics, or you would've thrown this book away in frustration! Frustration is natural when you start programming in R because it is such a stickler for punctuation, and even one character out of place will cause it to complain. But while you should expect to be a little frustrated, take comfort in that this experience is typical and temporary: it happens to everyone, and the only way to get over it is to keep trying.

Before we go any further, let's ensure you've got a solid foundation in running R code and that you know some of the most helpful RStudio features.

3.1 Coding basics

Let's review some basics we've omitted so far in the interest of getting you plotting as quickly as possible. You can use R as a calculator:

```
1 / 200 * 30
#> [1] 0.15
(59 + 73 + 2) / 3
#> [1] 44.66667
```

```
sin(pi / 2)  
#> [1] 1
```

You can create new objects with the assignment operator `<-`:

```
x <- 3 * 4
```

You can combine multiple elements into a vector with `c()`:

```
primes <- c(2, 3, 5, 7, 11, 13)
```

And basic arithmetic is applied to every element of the vector:

```
primes * 2  
#> [1] 4 6 10 14 22 26  
primes - 1  
#> [1] 1 2 4 6 10 12
```

All R statements where you create objects, **assignment** statements, have the same form:

```
object_name <- value
```

When reading that code, say “object name gets value” in your head.

You will make lots of assignments, and `<-` is a pain to type. You can save time with RStudio’s keyboard shortcut: Alt + - (the minus sign). Notice that RStudio automatically surrounds `<-` with spaces, which is a good code formatting practice. Code is miserable to read on a good day, so give you’re eyes a break and use spaces.

3.2 Comments

R will ignore any text after `#`. This allows you to write **comments**, text that is ignored by R but read by other humans. We'll sometimes include comments in examples explaining what's happening with the code.

Comments can be helpful for briefly describing what the following code does.

```
# define primes
primes <- c(2, 3, 5, 7, 11, 13)

# multiply primes by 2
primes * 2
#> [1] 4 6 10 14 22 26
```

With short pieces of code like this, leaving a comment for every single line of code might not be necessary. But as the code you're writing gets more complex, comments can save you (and your collaborators) a lot of time figuring out what was done in the code.

Use comments to explain the *why* of your code, not the *how* or the *what*. The *what* and *how* of your code are always possible to figure out, even if it might be tedious, by carefully reading it. But if you describe the “*what*” in your comments and your code, you’ll have to remember to update the comment and code in tandem carefully. If you change the code and forget to update the comment, they’ll be inconsistent, leading to confusion when you return to your code in the future.

Figuring out *why* something was done is much more difficult, if not impossible. For example, `geom_smooth()` has an argument called `span`, which controls the smoothness of the curve, with larger values yielding a smoother curve. Suppose you decide to change the value of `span` from its default of 0.75 to 0.3: it’s easy for a future reader to understand *what* is happening, but unless you note your thinking in a comment, no one will understand *why* you changed the default.

For data analysis code, use comments to explain your overall plan of attack and record important insights as you encounter them. There's no way to re-capture this knowledge from the code itself.

3.3 What's in a name?

Object names must start with a letter and can only contain letters, numbers, `_`, and `.`. You want your object names to be descriptive, so you'll need to adopt a convention for multiple words. We recommend **snake_case**, where you separate lowercase words with `_`.

```
i_use_snake_case  
otherPeopleUseCamelCase  
some.people.use.periods  
And_aFew.People_RENOUNCEconvention
```

We'll return to names again when we discuss code style in [Chapter 7](#).

You can inspect an object by typing its name:

```
x  
#> [1] 12
```

Make another assignment:

```
this_is_a_really_long_name <- 2.5
```

To inspect this object, try out RStudio's completion facility: type "this", press TAB, add characters until you have a unique prefix, then press return.

Ooops, you made a mistake! The value of `this_is_a_really_long_name` should be 3.5, not 2.5. Use another

keyboard shortcut to help you fix it. Type “this” then press Cmd/Ctrl + ↑. Doing so will list all the commands you’ve typed that start with those letters. Use the arrow keys to navigate, then press enter to retype the command. Change 2.5 to 3.5 and rerun.

Make yet another assignment:

```
r_rocks <- 2 ^ 3
```

Let’s try to inspect it:

```
r_rock  
#> Error: object 'r_rock' not found  
R_rocks  
#> Error: object 'R_rocks' not found
```

This illustrates the implied contract between you and R: R will do the tedious computations for you, but in exchange, you must be completely precise in your instructions. Typos matter; R can’t read your mind and say, “oh, they probably meant `r_rocks` when they typed `r_rock`”. Case matters; similarly, R can’t read your mind and say, “oh, they probably meant `r_rocks` when they typed `R_rocks`”.

3.4 Calling functions

R has a large collection of built-in functions that are called like this:

```
function_name(arg1 = val1, arg2 = val2, ...)
```

Let’s try using `seq()`, which makes regular **sequences** of numbers, and while we’re at it, learn more helpful features of RStudio. Type `se` and hit TAB. A popup shows you possible completions. Specify `seq()` by typing

more (a `q`) to disambiguate or by using \uparrow/\downarrow arrows to select. Notice the floating tooltip that pops up, reminding you of the function's arguments and purpose. If you want more help, press F1 to get all the details in the help tab in the lower right pane.

When you've selected the function you want, press TAB again. RStudio will add matching opening (`(`) and closing (`)`) parentheses for you. Type the arguments `1, 10` and hit return.

```
seq(1, 10)
#> [1] 1 2 3 4 5 6 7 8 9 10
```

Type this code and notice that RStudio provides similar assistance with the paired quotation marks:

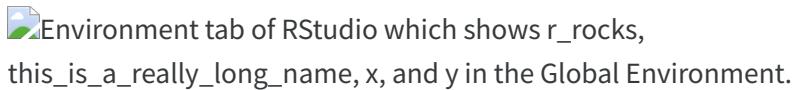

```
x <- "hello world"
```

Quotation marks and parentheses must always come in a pair. RStudio does its best to help you, but it's still possible to mess up and end up with a mismatch. If this happens, R will show you the continuation character “+”:

```
> x <- "hello
+
```

The `+` tells you that R is waiting for more input; it doesn't think you're done yet. Usually, this means you've forgotten either a `"` or a `)`. Either add the missing pair, or press ESCAPE to abort the expression and try again.

Note that the environment tab in the upper right pane displays all of the objects that you've created:

3.5 Exercises

1. Why does this code not work?

```
my_variable <- 10
my_variable
#> Error in eval(expr, envir, enclos): object 'my_va
```

Look carefully! (This may seem like an exercise in pointlessness, but training your brain to notice even the tiniest difference will pay off when programming.)

2. Tweak each of the following R commands so that they run correctly:

```
library(tidyverse)

ggplot(data = mpg) +
  geom_point(mapping = aes(x = displ, y = hwy))
```

3. Press Alt + Shift + K. What happens? How can you get to the same place using the menus?
4. Let's revisit an exercise from the [Section 2.6](#). Run the following lines of code. Which of the two plots is saved as `mpg-plot.png`? Why?

```
my_bar_plot <- ggplot(mpg, aes(x = class)) +
  geom_bar()
my_scatter_plot <- ggplot(mpg, aes(x = cty, y = hwy)
```

```
geom_point()  
ggsave(filename = "mpg-plot.png", plot = my_bar_plot
```

3.6 Summary

Now that you've learned a little more about how R code works, and some tips to help you understand your code when you come back to it in the future. In the next chapter, we'll continue your data science journey by teaching you about dplyr, the tidyverse package that helps you transform data, whether it's selecting important variables, filtering down to rows of interest, or computing summary statistics.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

4.1 Introduction

Visualisation is an important tool for generating insight, but it's rare that you get the data in exactly the right form you need for it. Often you'll need to create some new variables or summaries to see the most important patterns, or maybe you just want to rename the variables or reorder the observations to make the data a little easier to work with. You'll learn how to do all that (and more!) in this chapter, which will introduce you to data transformation using the **dplyr** package and a new dataset on flights that departed New York City in 2013.

The goal of this chapter is to give you an overview of all the key tools for transforming a data frame. We'll start with functions that operate on rows and then columns of a data frame. We will then introduce the ability to work with groups. We will end the chapter with a case study that showcases these functions in action and we'll come back to the functions in more detail in later chapters, as we start to dig into specific types of data (e.g. numbers, strings, dates).

4.1.1 Prerequisites

In this chapter we'll focus on the **dplyr** package, another core member of the tidyverse. We'll illustrate the key ideas using data from the

nycflights13 package, and use ggplot2 to help us understand the data.

```
library(nycflights13)
library(tidyverse)
#> — Attaching packages —————
#> ✓ ggplot2 3.4.0           ✓ purrr   1.0.1.9000
#> ✓ tibble   3.1.8           ✓ dplyr    1.0.99.9000
#> ✓ tidyr    1.2.1.9001      ✓ stringr 1.5.0
#> ✓ readr    2.1.3           ✓ forcats 0.5.2
#> — Conflicts —————
#> ✘ dplyr::filter() masks stats::filter()
#> ✘ dplyr::lag()   masks stats::lag()
```

Take careful note of the conflicts message that's printed when you load the tidyverse. It tells you that dplyr overwrites some functions in base R. If you want to use the base version of these functions after loading dplyr, you'll need to use their full names: `stats::filter()` and `stats::lag()`. So far we've mostly ignored which package a function comes from because most of the time it doesn't matter. However, knowing the package can help you find help and find related functions, so when we need to be precise about which function a package comes from, we'll use the same syntax as R:

```
packagename::functionname()
```

4.1.2 nycflights13

To explore the basic dplyr verbs, we're going to use `nycflights13::flights`. This dataset contains all 336,776 flights that departed from New York City in 2013. The data comes from the US [Bureau of Transportation Statistics](#), and is documented in `?flights`.

```
flights
#> # A tibble: 336,776 × 19
```

```
#>   year month   day dep_time sched_dep_time dep_delay arr_time
#>   <int> <int> <int>     <int>      <int>     <dbl>    <int>
#> 1 2013     1     1      517        515       2         830
#> 2 2013     1     1      533        529       4         850
#> 3 2013     1     1      542        540       2         923
#> 4 2013     1     1      544        545      -1        1004
#> 5 2013     1     1      554        600      -6         812
#> 6 2013     1     1      554        558      -4         740
#> # ... with 336,770 more rows, 9 more variables: flight
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   `^sched_dep_time`, `^dep_delay`, `^arr_time`, `^sched_ar
```

If you've used R before, you might notice that this data frame prints a little differently to other data frames you've seen. That's because it's a **tibble**, a special type of data frame used by the tidyverse to avoid some common gotchas. The most important difference is the way it prints: tibbles are designed for large datasets, so they only show the first few rows and only the columns that fit on one screen. There are a few options to see everything. If you're using RStudio, the most convenient is probably `View(flights)`, which will open an interactive scrollable and filterable view. Otherwise you can use `print(flights, width = Inf)` to show all columns, or use call `glimpse()`:

```
glimpse(flights)
#> Rows: 336,776
#> Columns: 19
#> $ year           <int> 2013, 2013, 2013, 2013, 2013,
#> $ month          <int> 1, 1, 1, 1, 1, 1, 1, 1, 1,
#> $ day            <int> 1, 1, 1, 1, 1, 1, 1, 1, 1,
#> $ dep_time        <int> 517, 533, 542, 544, 554, 554,
#> $ sched_dep_time <int> 515, 529, 540, 545, 600, 558,
#> $ dep_delay       <dbl> 2, 4, 2, -1, -6, -4, -5, -3, -
#> $ arr_time        <int> 830, 850, 923, 1004, 812, 740,
```

```
#> $ sched_arr_time <int> 819, 830, 850, 1022, 837, 728,  
#> $ arr_delay      <dbl> 11, 20, 33, -18, -25, 12, 19,  
#> $ carrier        <chr> "UA", "UA", "AA", "B6", "DL",  
#> $ flight         <int> 1545, 1714, 1141, 725, 461, 16  
#> $ tailnum        <chr> "N14228", "N24211", "N619AA",  
#> $ origin          <chr> "EWR", "LGA", "JFK", "JFK", "L  
#> $ dest            <chr> "IAH", "IAH", "MIA", "BQN", "A  
#> $ air_time        <dbl> 227, 227, 160, 183, 116, 150,  
#> $ distance        <dbl> 1400, 1416, 1089, 1576, 762, 7  
#> $ hour             <dbl> 5, 5, 5, 5, 6, 5, 6, 6, 6,  
#> $ minute           <dbl> 15, 29, 40, 45, 0, 58, 0, 0, 0  
#> $ time_hour       <dttm> 2013-01-01 05:00:00, 2013-01-
```

In both views, the variable names are followed by abbreviations that tell you the type of each variable: `<int>` is short for integer, `<dbl>` is short for double (aka real numbers), `<chr>` for character (aka strings), and `<dttm>` for date-time. These are important because the operations you can perform on a column depend so much on its “type”, and these types are used to organize the chapters in the next section of the book.

4.1.3 dplyr basics

You’re about to learn the primary dplyr verbs which will allow you to solve the vast majority of your data manipulation challenges. But before we discuss their individual differences, it’s worth stating what they have in common:

1. The first argument is always a data frame.
2. The subsequent arguments describe what to do with the data frame, using the variable names (without quotes).
3. The result is always a new data frame.

Because the first argument is a data frame and the output is a data frame, dplyr verbs work well with the pipe, `|>`. The pipe takes the thing on its left and passes it along to the function on its right so that `x |> f(y)` is equivalent to `f(x, y)`, and `x |> f(y) |> g(z)` is equivalent to `g(f(x, y), z)`. The easiest way to pronounce the pipe is “then”. That makes it possible to get a sense of the following code even though you haven’t yet learned the details:

```
flights |>
  filter(dest == "IAH") |>
  group_by(year, month, day) |>
  summarize(
    arr_delay = mean(arr_delay, na.rm = TRUE)
  )
```

The code starts with the `flights` dataset, then filters it, then groups it, then summarizes it. We’ll come back to the pipe and its alternatives in [Section 7.3](#).

dplyr’s verbs are organised into four groups based on what they operate on: **rows**, **columns**, **groups**, or **tables**. In the following sections you’ll learn the most important verbs for rows, columns, and groups, then we’ll come back to verbs that work on tables in [Chapter 21](#). Let’s dive in!

4.2 Rows

The most important verbs that operate on rows are `filter()`, which changes which rows are present without changing their order, and `arrange()`, which changes the order of the rows without changing which are present. Both functions only affect the rows, and the columns are left unchanged. We’ll also discuss `distinct()` which finds rows with unique values but unlike `arrange()` and `filter()` it can also optionally modify the columns.

4.2.1 filter()

`filter()` allows you to keep rows based on the values of the columns¹. The first argument is the data frame. The second and subsequent arguments are the conditions that must be true to keep the row. For example, we could find all flights that arrived more than 120 minutes (two hours) late:

```
flights |>
  filter(arr_delay > 120)
#> # A tibble: 10,034 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time
#>   <int> <int> <int>     <dbl>           <dbl>      <dbl>      <dbl>
#> 1 2013     1     1      811       630        101       1047
#> 2 2013     1     1      848      1835        853       1001
#> 3 2013     1     1      957       733        144       1056
#> 4 2013     1     1     1114       900        134       1447
#> 5 2013     1     1     1505      1310        115       1638
#> 6 2013     1     1     1525      1340        105       1831
#> # ... with 10,028 more rows, 9 more variables: flight <chr>,
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>,
#> #   minute <dbl>, time_hour <dttm>, and abbreviated version
#> #   1sched_dep_time, 2dep_delay, 3arr_time, 4sched_ar
```

As well as `>` (greater than), you can use `>=` (greater than or equal to), `<` (less than), `<=` (less than or equal to), `==` (equal to), and `!=` (not equal to). You can also use `&` (and) or `|` (or) to combine multiple conditions:

```
# Flights that departed on January 1
flights |>
  filter(month == 1 & day == 1)
#> # A tibble: 842 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time
#>   <int> <int> <int>     <dbl>           <dbl>      <dbl>      <dbl>
```

```

#>   <int> <int> <int>   <int>   <int>   <dbl>   <int>
#> 1  2013     1     1    517    515     2    830
#> 2  2013     1     1    533    529     4    850
#> 3  2013     1     1    542    540     2    923
#> 4  2013     1     1    544    545    -1   1004
#> 5  2013     1     1    554    600    -6    812
#> 6  2013     1     1    554    558    -4    740
#> # ... with 836 more rows, 9 more variables: flight <int>
#> #   origin <chr>, dest <chr>, air_time <dbl>, distanc
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   ^sched_dep_time, ^dep_delay, ^arr_time, ^sched_ar

# Flights that departed in January or February
flights |>
  filter(month == 1 | month == 2)
#> # A tibble: 51,955 × 19
#>   year month   day dep_time sched_...¹ dep_d...² arr_t...³
#>   <int> <int> <int>   <int>   <int>   <dbl>   <int>
#> 1  2013     1     1    517    515     2    830
#> 2  2013     1     1    533    529     4    850
#> 3  2013     1     1    542    540     2    923
#> 4  2013     1     1    544    545    -1   1004
#> 5  2013     1     1    554    600    -6    812
#> 6  2013     1     1    554    558    -4    740
#> # ... with 51,949 more rows, 9 more variables: flight <
#> #   origin <chr>, dest <chr>, air_time <dbl>, distanc
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   ^sched_dep_time, ^dep_delay, ^arr_time, ^sched_ar

```

There's a useful shortcut when you're combining `|` and `==`: `%in%`. It keeps rows where the variable equals one of the values on the right:

```

# A shorter way to select flights that departed in Janua
flights |>
  filter(month %in% c(1, 2))

```

```
#> # A tibble: 51,955 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time arr_delay
#>   <int> <int> <int>     <dbl>           <dbl>      <dbl>     <dbl>
#> 1 2013     1     1       517             515        2         830
#> 2 2013     1     1       533             529        4         850
#> 3 2013     1     1       542             540        2         923
#> 4 2013     1     1       544             545       -1        1004
#> 5 2013     1     1       554             600       -6        812
#> 6 2013     1     1       554             558       -4        740
#> # ... with 51,949 more rows, 9 more variables: flight <
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   `^sched_dep_time`, `^dep_delay`, `^arr_time`, `^sched_ar
```

We'll come back to these comparisons and logical operators in more detail in [Chapter 14](#).

When you run `filter()` dplyr executes the filtering operation, creating a new data frame, and then prints it. It doesn't modify the existing `flights` dataset because dplyr functions never modify their inputs. To save the result, you need to use the assignment operator, `<-`:

```
jan1 <- flights |>
  filter(month == 1 & day == 1)
```

4.2.2 Common mistakes

When you're starting out with R, the easiest mistake to make is to use `=` instead of `==` when testing for equality. `filter()` will let you know when this happens:

```
flights |>
  filter(month = 1)
#> Error in `filter()`:
```

```
#> ! We detected a named input.  
#> i This usually means that you've used `=` instead of  
#> i Did you mean `month == 1`?
```

Another mistakes is you write “or” statements like you would in English:

```
flights |>  
  filter(month == 1 | 2)
```

This works, in the sense that it doesn’t throw an error, but it doesn’t do what you want. We’ll come back to what it does and why in [Section 17.6.2](#).

4.2.3 `arrange()`

`arrange()` changes the order of the rows based on the value of the columns. It takes a data frame and a set of column names (or more complicated expressions) to order by. If you provide more than one column name, each additional column will be used to break ties in the values of preceding columns. For example, the following code sorts by the departure time, which is spread over four columns.

```
flights |>  
  arrange(year, month, day, dep_time)  
#> # A tibble: 336,776 × 19  
#>   year month   day dep_time sched_dep_time dep_delay arr_time dep_delay2 arr_time2  
#>   <int> <int> <int> <dbl> <dbl> <dbl> <dbl> <dbl> <dbl> <dbl>  
#> 1 2013     1     1     517      515        2       830  
#> 2 2013     1     1     533      529        4       850  
#> 3 2013     1     1     542      540        2       923  
#> 4 2013     1     1     544      545       -1      1004  
#> 5 2013     1     1     554      600       -6      812  
#> 6 2013     1     1     554      558       -4      740  
#> # ... with 336,770 more rows, 9 more variables: flight
```

```
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>, time_hour <dttm>, and abbreviated version of month_name
#> #   1sched_dep_time, 2dep_delay, 3arr_time, 4sched_arr_time
```

You can use `desc()` to re-order by a column in descending order. For example, this code shows the most delayed flights:

```
flights |>
  arrange(desc(dep_delay))
#> # A tibble: 336,776 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time
#>   <int> <int> <int> <int> <int> <dbl> <int>
#> 1 2013     1     9    641      900    1301    1242
#> 2 2013     6    15   1432     1935    1137    1607
#> 3 2013     1    10   1121     1635    1126    1239
#> 4 2013     9    20   1139     1845    1014    1457
#> 5 2013     7    22    845     1600    1005    1044
#> 6 2013     4    10   1100     1900     960    1342
#> # ... with 336,770 more rows, 9 more variables: flight <dbl>,
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>,
#> #   time_hour <dttm>, and abbreviated version of month_name
#> #   1sched_dep_time, 2dep_delay, 3arr_time, 4sched_arr_time
```

You can combine `arrange()` and `filter()` to solve more complex problems. For example, we could look for the flights that were most delayed on arrival that left on roughly on time:

```
flights |>
  filter(dep_delay <= 10 & dep_delay >= -10) |>
  arrange(desc(arr_delay))
#> # A tibble: 239,109 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time
#>   <int> <int> <int> <int> <int> <dbl> <int>
```

```
#> 1 2013 11 1 658 700 -2 1329
#> 2 2013 4 18 558 600 -2 1149
#> 3 2013 7 7 1659 1700 -1 2050
#> 4 2013 7 22 1606 1615 -9 2056
#> 5 2013 9 19 648 641 7 1035
#> 6 2013 4 18 655 700 -5 1213
#> # ... with 239,103 more rows, 9 more variables: flight
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   ^sched_dep_time, ^dep_delay, ^arr_time, ^sched_ar
```

4.2.4 `distinct()`

`distinct()` finds all the unique rows in a dataset, so in a technical sense, it primarily operates on the rows. Most of the time, however, you'll want the distinct combination of some variables, so you can also optionally supply column names:

```
# This would remove any duplicate rows if there were any
flights |>
  distinct()
#> # A tibble: 336,776 × 19
#>   year month   day dep_time sched_...¹ dep_d...² arr_t...³
#>   <int> <int> <int>     <int>     <int>     <dbl>     <int>
#> 1 2013     1     1      517      515       2     830
#> 2 2013     1     1      533      529       4     850
#> 3 2013     1     1      542      540       2     923
#> 4 2013     1     1      544      545      -1    1004
#> 5 2013     1     1      554      600      -6     812
#> 6 2013     1     1      554      558      -4     740
#> # ... with 336,770 more rows, 9 more variables: flight
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   ^sched_dep_time, ^dep_delay, ^arr_time, ^sched_ar
```

```
# This finds all unique origin and destination pairs.  
flights |>  
  distinct(origin, dest)  
#> # A tibble: 224 × 2  
#>   origin dest  
#>   <chr>  <chr>  
#> 1 EWR    IAH  
#> 2 LGA    IAH  
#> 3 JFK    MIA  
#> 4 JFK    BQN  
#> 5 LGA    ATL  
#> 6 EWR    ORD  
#> # ... with 218 more rows
```

Note that if you want to find the number of duplicates, or rows that weren't duplicated, you're better off swapping `distinct()` for `count()` and then filtering as needed.

4.2.5 Exercises

1. Find all flights that
 - a. Had an arrival delay of two or more hours
 - b. Flew to Houston (IAH or HOU)
 - c. Were operated by United, American, or Delta
 - d. Departed in summer (July, August, and September)
 - e. Arrived more than two hours late, but didn't leave late
 - f. Were delayed by at least an hour, but made up over 30 minutes in flight

2. Sort `flights` to find the flights with longest departure delays.

Find the flights that left earliest in the morning.

3. Sort `flights` to find the fastest flights (Hint: try sorting by a calculation).
4. Was there a flight on every day of 2013?
5. Which flights traveled the farthest distance? Which traveled the least distance?
6. Does it matter what order you used `filter()` and `arrange()` if you're using both? Why/why not? Think about the results and how much work the functions would have to do.

4.3 Columns

There are four important verbs that affect the columns without changing the rows: `mutate()`, `select()`, `rename()`, and `relocate()`. `mutate()` creates new columns that are functions of the existing columns; `select()`, `rename()`, and `relocate()` change which columns are present, their names, or their positions. We'll also discuss `pull()` since it allows you to get a column out of data frame.

4.3.1 `mutate()`

The job of `mutate()` is to add new columns that are calculated from the existing columns. In the transform chapters, you'll learn a large set of functions that you can use to manipulate different types of variables. For now, we'll stick with basic algebra, which allows us to compute the `gain`, how much time a delayed flight made up in the air, and the `speed` in miles per hour:

```
flights |>  
  mutate(  
    gain = dep_delay - arr_delay,
```

```

    speed = distance / air_time * 60
)
#> # A tibble: 336,776 × 21
#>   year month   day dep_time sched_dep_time1 dep_delay2 arr_time3
#>   <int> <int> <int>     <int>           <int>      <dbl>     <int>
#> 1 2013     1     1      517            515        2     830
#> 2 2013     1     1      533            529        4     850
#> 3 2013     1     1      542            540        2     923
#> 4 2013     1     1      544            545       -1    1004
#> 5 2013     1     1      554            600       -6     812
#> 6 2013     1     1      554            558       -4     740
#> # ... with 336,770 more rows, 11 more variables: flight
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, gain <dbl>, speed
#> #   variable names 1sched_dep_time, 2dep_delay, 3arr_
#> #   5arr_delay

```

By default, `mutate()` adds new columns on the right hand side of your dataset, which makes it difficult to see what's happening here. We can use the `.before` argument to instead add the variables to the left hand side²:

```

flights |>
  mutate(
    gain = dep_delay - arr_delay,
    speed = distance / air_time * 60,
    .before = 1
)
#> # A tibble: 336,776 × 21
#>   gain speed year month   day dep_time sched_dep_time1
#>   <dbl> <dbl> <int> <int> <int>           <int>      <dbl>
#> 1 -9   370.  2013     1     1      517            515
#> 2 -16  374.  2013     1     1      533            529
#> 3 -31  408.  2013     1     1      542            540
#> 4  17  517.  2013     1     1      544            545

```

```
#> 5    19  394.  2013     1     1    554      600
#> 6   -16  288.  2013     1     1    554      558
#> # ... with 336,770 more rows, 11 more variables: arr_de...
#> #   carrier <chr>, flight <int>, tailnum <chr>, origi...
#> #   air_time <dbl>, distance <dbl>, hour <dbl>, minut...
#> #   time_hour <dttm>, and abbreviated variable names ...
#> #     ^dep_delay, ^arr_time, ^sched_arr_time
```

The `.` is a sign that `.` before `is` an argument to the function, not the name of a new variable. You can also use `.after` to add after a variable, and in both `.before` and `.after` you can use the variable name instead of a position. For example, we could add the new variables after `day`:

```
flights |>
  mutate(
    gain = dep_delay - arr_delay,
    speed = distance / air_time * 60,
    .after = day
  )
#> # A tibble: 336,776 × 21
#>   year month   day gain speed dep_time sched_dep_...¹
#>   <int> <int> <int> <dbl> <dbl>     <int>        <int>
#> 1 2013     1     1    -9  370.      517        515
#> 2 2013     1     1   -16  374.      533        529
#> 3 2013     1     1   -31  408.      542        540
#> 4 2013     1     1    17  517.      544        545
#> 5 2013     1     1    19  394.      554        600
#> 6 2013     1     1   -16  288.      554        558
#> # ... with 336,770 more rows, 11 more variables: arr_de...
#> #   carrier <chr>, flight <int>, tailnum <chr>, origi...
#> #   air_time <dbl>, distance <dbl>, hour <dbl>, minut...
```

```
#> #   time_hour <dttm>, and abbreviated variable names  
#> #   ^dep_delay, ^arr_time, ^sched_arr_time
```

Alternatively, you can control which variables are kept with the `.keep` argument. A particularly useful argument is "used" which allows you to see the inputs and outputs from your calculations:

```
flights |>  
  mutate(  
    gain = dep_delay - arr_delay,  
    hours = air_time / 60,  
    gain_per_hour = gain / hours,  
    .keep = "used"  
)  
#> # A tibble: 336,776 × 6  
#>   dep_delay arr_delay air_time gain hours gain_per_h  
#>       <dbl>      <dbl>     <dbl> <dbl> <dbl>        <dbl>  
#> 1         2          11      227    -9   3.78        -2  
#> 2         4          20      227   -16   3.78        -4  
#> 3         2          33      160   -31   2.67       -11  
#> 4        -1         -18      183    17   3.05         5  
#> 5        -6         -25      116    19   1.93         9  
#> 6        -4          12      150   -16   2.5        -6  
#> # ... with 336,770 more rows
```

4.3.2 `select()`

It's not uncommon to get datasets with hundreds or even thousands of variables. In this situation, the first challenge is often just focusing on the variables you're interested in. `select()` allows you to rapidly zoom in on a useful subset using operations based on the names of the variables. `select()` is not terribly useful with the flights data because

we only have 19 variables, but you can still get the general idea of how it works:

```
# Select columns by name
flights |>
  select(year, month, day)
#> # A tibble: 336,776 × 3
#>   year month   day
#>   <int> <int> <int>
#> 1  2013     1     1
#> 2  2013     1     1
#> 3  2013     1     1
#> 4  2013     1     1
#> 5  2013     1     1
#> 6  2013     1     1
#> # ... with 336,770 more rows

# Select all columns between year and day (inclusive)
flights |>
  select(year:day)
#> # A tibble: 336,776 × 3
#>   year month   day
#>   <int> <int> <int>
#> 1  2013     1     1
#> 2  2013     1     1
#> 3  2013     1     1
#> 4  2013     1     1

#> 5    554        600       -6         812        837       -2
#> 6    554        558       -4         740        728        1
#> # ... with 336,770 more rows, 7 more variables: origin
#> #   air_time <dbl>, distance <dbl>, hour <dbl>, minut
#> #   time_hour <dttm>, and abbreviated variable names
#> #   ^dep_delay, ^arr_time, ^sched_arr_time, ^arr_dela

# Select all columns that are characters
flights |>
  select(where(is.character))
#> # A tibble: 336,776 × 4
#>   carrier tailnum origin dest
#>   <chr>    <chr>    <chr>   <chr>
#> 1 UA       N14228   EWR     IAH
#> 2 UA       N24211   LGA     IAH
#> 3 AA       N619AA   JFK     MIA
#> 4 B6       N804JB   JFK     BQN
#> 5 DL       N668DN   LGA     ATL
#> 6 UA       N39463   EWR     ORD
#> # ... with 336,770 more rows

```

There are a number of helper functions you can use within `select()`:

- `starts_with("abc")` : matches names that begin with “abc”.
- `ends_with("xyz")` : matches names that end with “xyz”.
- `contains("ijk")` : matches names that contain “ijk”.
- `num_range("x", 1:3)` : matches x1, x2 and x3.

See `?select` for more details. Once you know regular expressions (the topic of [Chapter 17](#)) you’ll also be able to use `matches()` to select

variables that match a pattern.

You can rename variables as you `select()` them by using `=`. The new name appears on the left hand side of the `=`, and the old variable appears on the right hand side:

```
flights |>
  select(tail_num = tailnum)
#> # A tibble: 336,776 × 1
#>   tail_num
#>   <chr>
#> 1 N14228
#> 2 N24211
#> 3 N619AA
#> 4 N804JB
#> 5 N668DN
#> 6 N39463
#> # ... with 336,770 more rows
```

4.3.3 `rename()`

If you just want to keep all the existing variables and just want to rename a few, you can use `rename()` instead of `select()`:

```
flights |>
  rename(tail_num = tailnum)
#> # A tibble: 336,776 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time arr_delay
#>   <int> <int> <int>    <dbl>        <dbl>      <dbl>    <dbl>      <dbl>
#> 1  2013     1     1      517        515       2        830
#> 2  2013     1     1      533        529       4        850
#> 3  2013     1     1      542        540       2        923
#> 4  2013     1     1      544        545      -1       1004
#> 5  2013     1     1      554        600      -6        812
#> 6  2013     1     1      554        558      -4        740
#> # ... with 336,770 more rows, 9 more variables: flight
```

```
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>, minute <dbl>, time_hour <dttm>, and abbreviated version of sched_dep_time, dep_delay, arr_time, sched_arr_time
```

It works exactly the same way as `select()`, but keeps all the variables that aren't explicitly selected.

If you have a bunch of inconsistently named columns and it would be painful to fix them all by hand, check out `janitor::clean_names()` which provides some useful automated cleaning.

4.3.4 `relocate()`

Use `relocate()` to move variables around. You might want to collect related variables together or move important variables to the front. By default `relocate()` moves variables to the front:

```
flights |>
  relocate(time_hour, air_time)
#> # A tibble: 336,776 × 19
#>   time_hour           air_time   year month   day dep_
#>   <dttm>             <dbl> <int> <int> <int>   <
#> 1 2013-01-01 05:00:00     227  2013      1      1
#> 2 2013-01-01 05:00:00     227  2013      1      1
#> 3 2013-01-01 05:00:00     160  2013      1      1
#> 4 2013-01-01 05:00:00     183  2013      1      1
#> 5 2013-01-01 06:00:00     116  2013      1      1
#> 6 2013-01-01 05:00:00     150  2013      1      1
#> # ... with 336,770 more rows, 11 more variables: arr_time <dbl>, sched_arr_time <int>, arr_delay <dbl>, carrier <chr>, tailnum <chr>, origin <chr>, dest <chr>, distance <dbl>, minute <dbl>, and abbreviated variable names `sch`
```

But you can use the same `.before` and `.after` arguments as `mutate()` to choose where to put them:

```
flights |>
  relocate(year:dep_time, .after = time_hour)
#> # A tibble: 336,776 × 19
#>   sched...¹ dep_d...² arr_t...³ sched...⁴ arr_d...⁵ carrier fli
#>   <int>    <dbl>    <int>    <int>    <dbl> <chr>    <i
#> 1     515      2     830     819      11  UA       1
#> 2     529      4     850     830      20  UA       1
#> 3     540      2     923     850      33  AA       1
#> 4     545     -1    1004    1022     -18  B6
#> 5     600     -6     812     837     -25  DL
#> 6     558     -4     740     728      12  UA       1
#> # ... with 336,770 more rows, 9 more variables: air_time
#> #   distance <dbl>, hour <dbl>, minute <dbl>, time_hour
#> #   month <int>, day <int>, dep_time <int>, and abbrev
#> #   `¹sched_dep_time`, `²dep_delay`, `³arr_time`, `⁴sched_ar
flights |>
  relocate(starts_with("arr"), .before = dep_time)
#> # A tibble: 336,776 × 19
#>   year month   day arr_time arr_de...¹ dep_t...² sched...³
#>   <int> <int> <int>    <int>    <dbl>    <int>    <int>
#> 1  2013     1     1     830      11      517      515
#> 2  2013     1     1     850      20      533      529
#> 3  2013     1     1     923      33      542      540
#> 4  2013     1     1    1004     -18      544      545
#> 5  2013     1     1     812     -25      554      600
#> 6  2013     1     1     740      12      554      558
#> # ... with 336,770 more rows, 9 more variables: flight
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   `¹arr_delay`, `²dep_time`, `³sched_dep_time`, `⁴dep_delay`
```

4.3.5 Exercises

1. Compare `air_time` with `arr_time - dep_time`. What do you expect to see? What do you see? What do you need to do to fix it?
2. Compare `dep_time`, `sched_dep_time`, and `dep_delay`. How would you expect those three numbers to be related?
3. Brainstorm as many ways as possible to select `dep_time`, `dep_delay`, `arr_time`, and `arr_delay` from `flights`.
4. What happens if you include the name of a variable multiple times in a `select()` call?
5. What does the `any_of()` function do? Why might it be helpful in conjunction with this vector?

```
variables <- c("year", "month", "day", "dep_delay",
```

6. Does the result of running the following code surprise you? How do the select helpers deal with case by default? How can you change that default?

```
select(flights, contains("TIME"))
```

4.4 Groups

So far you've learned about functions that work with rows and columns. dplyr gets even more powerful when you add in the ability to work with groups. In this section, we'll focus on the most important functions: `group_by()`, `summarize()`, and the slice family of functions.

4.4.1 group_by()

Use `group_by()` to divide your dataset into groups meaningful for your analysis:

```
flights |>
  group_by(month)

#> # A tibble: 336,776 × 19
#> # Groups: month [12]
#>   year month   day dep_time sched_dep_time1 dep_delay2 arr_time3
#>   <int> <int> <int>     <dbl>           <dbl>      <dbl>        <dbl>
#> 1 2013     1     1      517            515       2         830
#> 2 2013     1     1      533            529       4         850
#> 3 2013     1     1      542            540       2         923
#> 4 2013     1     1      544            545      -1        1004
#> 5 2013     1     1      554            600      -6        812
#> 6 2013     1     1      554            558      -4        740
#> # ... with 336,770 more rows, 9 more variables: flight4, origin<chr>, dest<chr>, air_time<dbl>, distance<dbl>, minute<dbl>, time_hour<dttm>, and abbreviated version5
#> #   ^ sched_dep_time, ^ dep_delay, ^ arr_time, ^ sched_arr_time, ^ arr_delay, ^ distance, ^ time_hour, ^ minute, ^ origin, ^ dest
```

`group_by()` doesn't change the data but, if you look closely at the output, you'll notice that it's now "grouped by" month. This means subsequent operations will now work "by month". `group_by()` doesn't do anything by itself; instead it changes the behavior of the subsequent verbs.

4.4.2 summarize()

The most important grouped operation is a summary, which collapses each group to a single row. In dplyr, this operation is performed by

`summarize()`³, as shown by the following example, which computes the average departure delay by month:

```
flights |>
  group_by(month) |>
  summarize(
    delay = mean(dep_delay)
  )
#> # A tibble: 12 × 2
#>   month   delay
#>   <int> <dbl>
#> 1     1     NA
#> 2     2     NA
#> 3     3     NA
#> 4     4     NA
#> 5     5     NA
#> 6     6     NA
#> # ... with 6 more rows
```

Uhoh! Something has gone wrong and all of our results are `NA` (pronounced “N-A”), R’s symbol for missing value. We’ll come back to discuss missing values in [Chapter 20](#), but for now we’ll remove them by using `na.rm = TRUE`:

```
flights |>
  group_by(month) |>
  summarize(
    delay = mean(dep_delay, na.rm = TRUE)
  )
#> # A tibble: 12 × 2
#>   month   delay
#>   <int> <dbl>
#> 1     1  10.0
#> 2     2  10.8
#> 3     3  13.2
```

```
#> 4      4  13.9  
#> 5      5  13.0  
#> 6      6  20.8  
#> # ... with 6 more rows
```

You can create any number of summaries in a single call to `summarize()`. You'll learn various useful summaries in the upcoming chapters, but one very useful summary is `n()`, which returns the number of rows in each group:

```
flights |>  
  group_by(month) |>  
  summarize(  
    delay = mean(dep_delay, na.rm = TRUE),  
    n = n()  
  )  
#> # A tibble: 12 × 3  
#>   month  delay     n  
#>   <int> <dbl> <int>  
#> 1     1  10.0  27004  
#> 2     2  10.8  24951  
#> 3     3  13.2  28834  
#> 4     4  13.9  28330  
#> 5     5  13.0  28796  
#> 6     6  20.8  28243  
#> # ... with 6 more rows
```

Means and counts can get you a surprisingly long way in data science!

4.4.3 The `slice_` functions

There are five handy functions that allow you pick off specific rows within each group:

- `df |> slice_head(n = 1)` takes the first row from each group.
- `df |> slice_tail(n = 1)` takes the last row in each group.

- `df |> slice_min(x, n = 1)` takes the row with the smallest value of `x`.
- `df |> slice_max(x, n = 1)` takes the row with the largest value of `x`.
- `df |> slice_sample(n = 1)` takes one random row.

You can vary `n` to select more than one row, or instead of `n =`, you can use `prop = 0.1` to select (e.g.) 10% of the rows in each group. For example, the following code finds the most delayed flight to each destination:

```
flights |>
  group_by(dest) |>
  slice_max(arr_delay, n = 1)
#> # A tibble: 108 × 19
#> # Groups:   dest [105]
#>   year month   day dep_time sched_dep_time1 dep_delay2 arr_time3
#>   <int> <int> <int>     <dbl>      <dbl>       <dbl>      <dbl>
#> 1 2013     7    22     2145      2007        98     132
#> 2 2013     7    23     1139      800       219     1250
#> 3 2013     1    25      123      2000       323     229
#> 4 2013     8    17     1740      1625        75     2042
#> 5 2013     7    22     2257      759       898     121
#> 6 2013     7    10     2056      1505       351     2347
#> # ... with 102 more rows, 9 more variables: flight <int>,
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>,
#> #   minute <dbl>, time_hour <dttm>, and abbreviated version
#> #   1sched_dep_time, 2dep_delay, 3arr_time, 4sched_ar
```

This is similar to computing the max delay with `summarize()`, but you get the whole row instead of the single summary:

```
flights |>
  group_by(dest) |>
  summarize(max_delay = max(arr_delay, na.rm = TRUE))
#> Warning: There was 1 warning in `summarize()` .
#> i In argument: `max_delay = max(arr_delay, na.rm = TRUE)` .
#> i In group 52: `dest = "LGA"` .
#> Caused by warning in `max()` :
#> ! no non-missing arguments to max; returning -Inf
#> # A tibble: 105 × 2
#>   dest    max_delay
#>   <chr>     <dbl>
#> 1 ABQ        153
#> 2 ACK        221
#> 3 ALB        328
#> 4 ANC         39
#> 5 ATL       895
#> 6 AUS        349
#> # ... with 99 more rows
```

4.4.4 Grouping by multiple variables

You can create groups using more than one variable. For example, we could make a group for each day:

```
daily <- flights |>
  group_by(year, month, day)
daily
#> # A tibble: 336,776 × 19
#> # Groups:   year, month, day [365]
#>   year month   day dep_time sched_dep_time dep_delay arr_delay
#>   <int> <int> <int>     <int>      <dbl>     <dbl>
#> 1 2013     1     1      517        515        2     830
#> 2 2013     1     1      533        529        4     850
```

```
#> 3 2013    1    1    542    540    2    923
#> 4 2013    1    1    544    545    -1   1004
#> 5 2013    1    1    554    600    -6    812
#> 6 2013    1    1    554    558    -4    740
#> # ... with 336,770 more rows, 9 more variables: flight
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, and abbreviated version
#> #   `^sched_dep_time`, `^dep_delay`, `^arr_time`, `^sched_ar
```

When you summarize a tibble grouped by more than one variable, each summary peels off the last group. In hindsight, this wasn't great way to make this function work, but it's difficult to change without breaking existing code. To make it obvious what's happening, dplyr displays a message that tells you how you can change this behavior:

```
daily_flights <- daily |>
  summarise(
    n = n()
  )
#> `summarise()` has grouped output by 'year', 'month'.
#> the `.groups` argument.
```

If you're happy with this behavior, you can explicitly request it in order to suppress the message:

```
daily_flights <- daily |>
  summarise(
    n = n(),
    .groups = "drop_last"
  )
```

Alternatively, change the default behavior by setting a different value, e.g. "drop" to drop all grouping or "keep" to preserve the same groups.

4.4.5 Ungrouping

You might also want to remove grouping outside of `summarize()`. You can do this with `ungroup()`.

```
daily |>
  ungroup() |>
  summarize(
    delay = mean(dep_delay, na.rm = TRUE),
    flights = n()
  )
#> # A tibble: 1 × 2
#>   delay flights
#>   <dbl>    <int>
#> 1  12.6    336776
```

As you can see, when you summarize an ungrouped data frame, you get a single row back because dplyr treats all the rows in an ungrouped data frame as belonging to one group.

4.4.6 Exercises

1. Which carrier has the worst delays? Challenge: can you disentangle the effects of bad airports vs. bad carriers? Why/why not? (Hint: think about `flights |> group_by(carrier, dest) |> summarize(n())`)
2. Find the most delayed flight to each destination.
3. How do delays vary over the course of the day. Illustrate your answer with a plot.

4. What happens if you supply a negative `n` to `slice_min()` and friends?
5. Explain what `count()` does in terms of the dplyr verbs you just learn. What does the `sort` argument to `count()` do?
6. Suppose we have the following tiny data frame:

```
df <- tibble(  
  x = 1:5,  
  y = c("a", "b", "a", "a", "b"),  
  z = c("K", "K", "L", "L", "K"))
```

- a. What does the following code do? Run it, analyze the result, and describe what `group_by()` does.

```
df |>  
  group_by(y)
```

- b. What does the following code do? Run it, analyze the result, and describe what `arrange()` does. Also comment on how it's different from the `group_by()` in part (a)?

```
df |>  
  arrange(y)
```

- c. What does the following code do? Run it, analyze the result, and describe what the pipeline does.

```
df |>  
  group_by(y) |>  
  summarize(mean_x = mean(x))
```

d. What does the following code do? Run it, analyze the result, and describe what the pipeline does. Then, comment on what the message says.

```
df |>  
  group_by(y, z) |>  
  summarize(mean_x = mean(x))
```

e. What does the following code do? Run it, analyze the result, and describe what the pipeline does. How is the output different from the one in part (d).

```
df |>  
  group_by(y, z) |>  
  summarize(mean_x = mean(x), .groups = "drop")
```

f. What do the following pipelines do? Run both, analyze the results, and describe what each pipeline does. How are the outputs of the two pipelines different?

```
df |>  
  group_by(y, z) |>  
  summarize(mean_x = mean(x))  
  
df |>  
  group_by(y, z) |>  
  mutate(mean_x = mean(x))
```

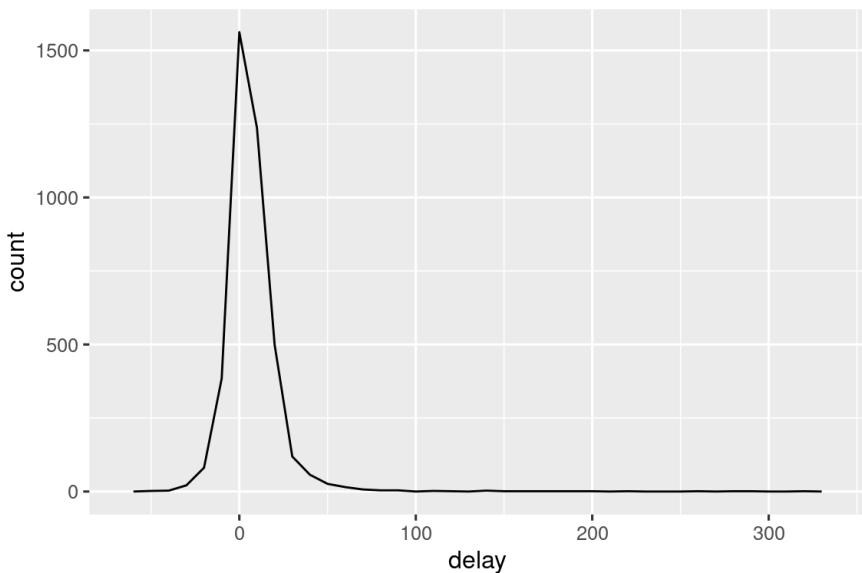

4.5 Case study: aggregates and sample size

Whenever you do any aggregation, it's always a good idea to include a count (`n()`). That way, you can ensure that you're not drawing conclusions based on very small amounts of data. For example, let's

look at the planes (identified by their tail number) that have the highest average delays:

```
delays <- flights |>
  filter(!is.na(arr_delay), !is.na(tailnum)) |>
  group_by(tailnum) |>
  summarize(
    delay = mean(arr_delay, na.rm = TRUE),
    n = n()
  )

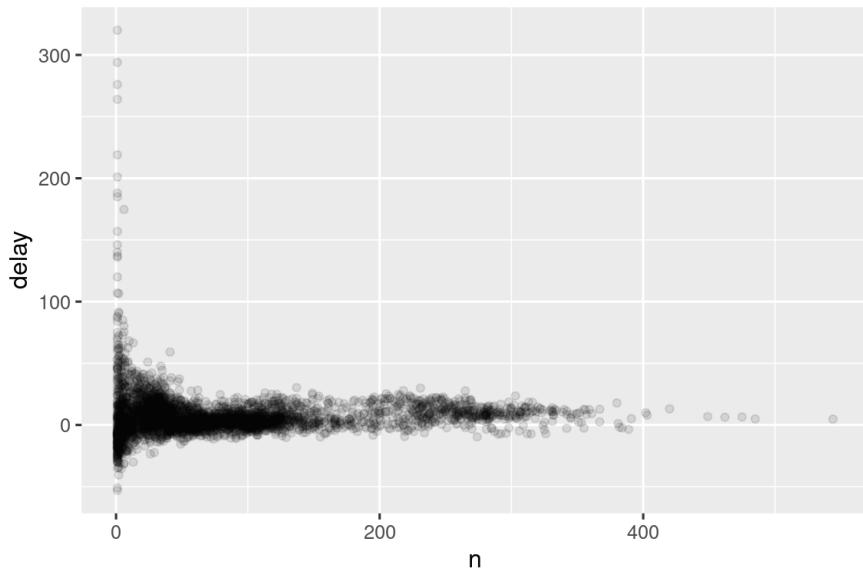

ggplot(delays, aes(x = delay)) +
  geom_freqpoly(binwidth = 10)
```

Wow, there are some planes that have an *average* delay of 5 hours (300 minutes)! That seems pretty surprising, so lets draw a scatterplot of number of flights vs. average delay:

```
ggplot(delays, aes(x = n, y = delay)) +
```

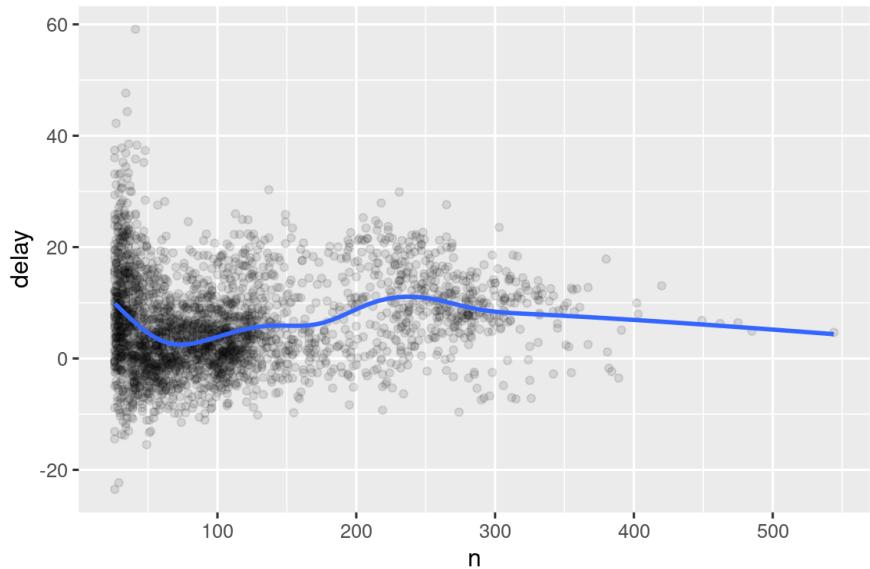

```
geom_point(alpha = 1/10)
```

Not surprisingly, there is much greater variation in the average delay when there are few flights for a given plane. The shape of this plot is very characteristic: whenever you plot a mean (or other summary) vs. group size, you'll see that the variation decreases as the sample size increases⁴.

When looking at this sort of plot, it's often useful to filter out the groups with the smallest numbers of observations, so you can see more of the pattern and less of the extreme variation in the smallest groups:

```
delays |>
  filter(n > 25) |>
  ggplot(aes(x = n, y = delay)) +
  geom_point(alpha = 1/10) +
  geom_smooth(se = FALSE)
```

Note the handy pattern for combining ggplot2 and dplyr. It's a bit annoying that you have to switch from `|>` to `+`, but it's not too much of a hassle once you get the hang of it.

There's another common variation on this pattern that we can see in some data about baseball players. The following code uses data from the **Lahman** package to compare what proportion of times a player hits the ball vs. the number of attempts they take:

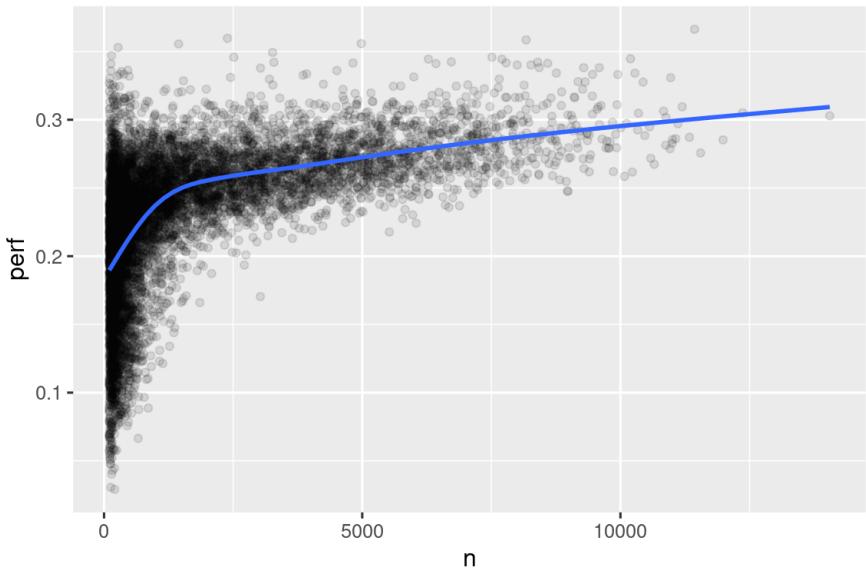

```
batters <- Lahman::Batting |>
  group_by(playerID) |>
  summarize(
    perf = sum(H, na.rm = TRUE) / sum(AB, na.rm = TRUE),
    n = sum(AB, na.rm = TRUE)
  )
batters
#> # A tibble: 20,166 × 3
#>   playerID      perf      n
#>   <chr>      <dbl>  <int>
#> 1 aardsda01 0         4
```

```
#> 2 aaronha01 0.305 12364  
#> 3 aaronto01 0.229 944  
#> 4 aasedo01 0 5  
#> 5 abadan01 0.0952 21  
#> 6 abadfe01 0.111 9  
#> # ... with 20,160 more rows
```

When we plot the skill of the batter (measured by the batting average, `ba`) against the number of opportunities to hit the ball (measured by `at_bat`, `ab`), you see two patterns:

1. As above, the variation in our aggregate decreases as we get more data points.
2. There's a positive correlation between skill (`perf`) and opportunities to hit the ball (`n`) because obviously teams want to give their best batters the most opportunities to hit the ball.

```
batters |>  
  filter(n > 100) |>  
  ggplot(aes(x = n, y = perf)) +  
    geom_point(alpha = 1 / 10) +  
    geom_smooth(se = FALSE)
```

This also has important implications for ranking. If you naively sort on `desc(ba)`, the people with the best batting averages are clearly lucky, not skilled:

```
batters |>
  arrange(desc(perf))
#> # A tibble: 20,166 × 3
#>   playerID    perf      n
#>   <chr>     <dbl> <int>
#> 1 abramge01     1      1
#> 2 alberan01     1      1
#> 3 banisje01     1      1
#> 4 bartocl01     1      1
#> 5 bassdo01     1      1
#> 6 birasst01     1      2
#> # ... with 20,160 more rows
```

You can find a good explanation of this problem and how to overcome it at http://varianceexplained.org/r/empirical_bayes_baseball/ and <https://www.evanmiller.org/how-not-to-sort-by-average-rating.html>.

4.6 Summary

In this chapter, you've learned the tools that dplyr provides for working with data frames. The tools are roughly grouped into three categories: those that manipulate the rows (like `filter()` and `arrange()`), those that manipulate the columns (like `select()` and `mutate()`), and those that manipulate groups (like `group_by()` and `summarize()`). In this chapter, we've focused on these “whole data frame” tools, but you haven't yet learned much about what you can do with the individual variable. We'll come back to that in the Transform part of the book, where each chapter will give you tools for a specific type of variable.

For now, we'll pivot back to workflow, and in the next chapter you'll learn more about the pipe, `|>`, why we recommend it, and a little of the history that lead from magrittr's `%>%` to base R's `|>`.

1. Later, you'll learn about the `slice_*`() family which allows you to choose rows based on their positions. 
2. Remember that in RStudio, the easiest way to see a dataset with many columns is `View()`. 
3. Or `summarise()`, if you prefer British English. 
4. *cough* the central limit theorem *cough*. 

5 Workflow: pipes

>

i You are reading the work-in-progress second edition of R for Data Science. This chapter is largely complete and just needs final proof reading. You can find the complete first edition at <https://r4ds.had.co.nz>.

The pipe, `|>`, is a powerful tool for clearly expressing a sequence of operations that transform an object. We briefly introduced pipes in the previous chapter, but before going further, we want to give a few more details and discuss `%>%`, a predecessor to `|>`.

To add the pipe to your code, we recommend using the build-in keyboard shortcut Ctrl/Cmd + Shift + M. You'll need to make one change to your RStudio options to use `|>` instead of `%>%` as shown in [Figure 5.1](#); more on `%>%` shortly.

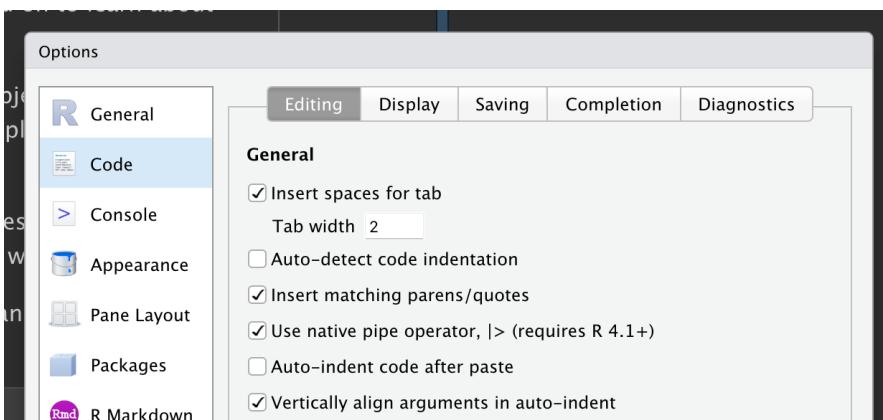

Figure 5.1: To insert `|>`, make sure the “Use native pipe operator” option is checked.

5.1 Why use a pipe?

Each individual dplyr verb is quite simple, so solving complex problems typically requires combining multiple verbs. For example, the last chapter finished with a moderately complex pipe:

```
flights |>
  filter(!is.na(arr_delay), !is.na(tailnum)) |>
  group_by(tailnum) |>
  summarize(
    delay = mean(arr_delay, na.rm = TRUE),
    n = n()
  )
```

Even though this pipe has four steps, it's easy to skim because the verbs come at the start of each line: start with the `flights` data, then filter, then group, then summarize.

What would happen if we didn't have the pipe? We could nest each function call inside the previous call:

```
summarize(
  group_by(
    filter(
      flights,
      !is.na(arr_delay), !is.na(tailnum)
    ),
    tailnum
  ),
  delay = mean(arr_delay, na.rm = TRUE
  ),
  n = n()
)
```

Or we could use a bunch of intermediate variables:

```
flights1 <- filter(flights, !is.na(arr_delay), !is.na(tailnum))
flights2 <- group_by(flights1, tailnum)
flights3 <- summarize(flights2,
  delay = mean(arr_delay, na.rm = TRUE),
  n = n()
)
```

While both forms have their time and place, the pipe generally produces data analysis code that is easier to write and read.

5.2 magrittr and the `%>%` pipe

If you've been using the tidyverse for a while, you might be familiar with the `%>%` pipe provided by the **magrittr** package. The magrittr package is included in the core tidyverse, so you can use `%>%` whenever you load the tidyverse:

```
library(tidyverse)
```

```
mtcars %>%
  group_by(cyl) %>%
  summarize(n = n())
#> # A tibble: 3 × 2
#>   cyl     n
#>   <dbl> <int>
#> 1     4     11
#> 2     6      7
#> 3     8     14
```

For simple cases, `|>` and `%>%` behave identically. So why do we recommend the base pipe? Firstly, because it's part of base R, it's always available for you to use, even when you're not using the tidyverse. Secondly, `|>` is quite a bit simpler than `%>%`: in the time between the invention of `%>%` in 2014 and the inclusion of `|>` in R 4.1.0 in 2021, we gained a better understanding of the pipe. This allowed the base implementation to jettison infrequently used and less important features.

5.3 `|> vs. %>%`

While `|>` and `%>%` behave identically for simple cases, there are a few crucial differences. These are most likely to affect you if you're a long-term user of `%>%` who has taken advantage of some of the more advanced features. But they're still good to know about even if you've never used `%>%` because you're likely to encounter some of them when reading wild-caught code.

- By default, the pipe passes the object on its left-hand side to the first argument of the function on the right-hand side. `%>%` allows you to change the placement with a `.` placeholder. For example, `x %>% f(1)` is equivalent to `f(x, 1)` but `x %>% f(1, .)` is equivalent to `f(1, x)`. R 4.2.0 added a `_` placeholder to the base pipe, with one additional restriction: the argument has to be named. For example, `x |> f(1, y = _)` is equivalent to `f(1, y = x)`.
- The `|>` placeholder is deliberately simple and can't replicate many features of the `%>%` placeholder: you can't pass it to multiple arguments, and it doesn't have any special behavior when the placeholder is used inside another function. For example, `df %>%`

`split(.var)` is equivalent to `split(df, df$var)` and `df %>% {split(.x, .y)}` is equivalent to `split(dfx, dfy)`.

With `%>%`, you can use `.` on the left-hand side of operators like `$`, `[`, `[` (which you'll learn about in [Section 29.1](#)), so you can extract a single column from a data frame with (e.g.) `mtcars %>% .cyl`. A future version of R may add similar support for `|>` and `_`. For the special case of extracting a column out of a data frame, you can also use `dplyr::pull()`:

```
mtcars |> pull(cyl)
#> [1] 6 6 4 6 8 6 8 4 4 6 6 8 8 8 8 8 8 4 4 4 4 8
```

- `%>%` allows you to drop the parentheses when calling a function with no other arguments; `|>` always requires the parentheses.
- `%>%` allows you to start a pipe with `.` to create a function rather than immediately executing the pipe; this is not supported by the base pipe.

Luckily there's no need to commit entirely to one pipe or the other — you can use the base pipe for the majority of cases where it's sufficient and use the magrittr pipe when you really need its special features.

5.4 |> vs +

Sometimes we'll turn the end of a data transformation pipeline into a plot. Watch for the transition from `|>` to `+`. We wish this transition wasn't necessary, but unfortunately, ggplot2 was created before the pipe was discovered.

```
diamonds |>  
  count(cut, clarity) |>  
  ggplot(aes(x = clarity, y = cut, fill = n)) +  
  geom_tile()
```

5.5 Summary

In this chapter, you've learned more about the pipe: why we recommend it and some of the history that lead to `|>`. The pipe is important because you'll use it again and again throughout your analysis, but hopefully, it will quickly become invisible, and your fingers will type it (or use the keyboard shortcut) without your brain having to think too much about it.

In the next chapter, we switch back to data science tools, learning about tidy data. Tidy data is a consistent way of organizing your data frames that is used throughout the tidyverse. This consistency makes your life easier because once you have tidy data, it just works with the vast majority of tidyverse functions. Of course, life is never easy, and most datasets you encounter in the wild will not already be tidy. So we'll also teach you how to use the `tidyverse` package to tidy your untidy data.

 You are reading the work-in-progress second edition of R for Data Science. This chapter is largely complete and just needs final proof reading. You can find the complete first edition at <https://r4ds.had.co.nz>.

6.1 Introduction

“Happy families are all alike; every unhappy family is unhappy in its own way.”

— Leo Tolstoy

“Tidy datasets are all alike, but every messy dataset is messy in its own way.”

— Hadley Wickham

In this chapter, you will learn a consistent way to organize your data in R using a system called **tidy data**. Getting your data into this format requires some work up front, but that work pays off in the long term. Once you have tidy data and the tidy tools provided by packages in the tidyverse, you will spend much less time munging data from one representation to another, allowing you to spend more time on the data questions you care about.

In this chapter, you’ll first learn the definition of tidy data and see it applied to a simple toy dataset. Then we’ll dive into the primary tool you’ll use for tidying data: pivoting. Pivoting allows you to change the

form of your data without changing any of the values. We'll finish with a discussion of usefully untidy data and how you can create it if needed.

6.1.1 Prerequisites

In this chapter, we'll focus on `tidyverse`, a package that provides a bunch of tools to help tidy up your messy datasets. `tidyverse` is a member of the core `tidyverse`.

```
library(tidyverse)
```

From this chapter on, we'll suppress the loading message from `library(tidyverse)`.

6.2 Tidy data

You can represent the same underlying data in multiple ways. The example below shows the same data organized in four different ways. Each dataset shows the same values of four variables: *country*, *year*, *population*, and *cases* of TB (tuberculosis), but each dataset organizes the values in a different way.

```
table1
#> # A tibble: 6 × 4
#>   country      year  cases population
#>   <chr>        <dbl> <dbl>       <dbl>
#> 1 Afghanistan  1999    745  19987071
#> 2 Afghanistan  2000   2666  20595360
#> 3 Brazil        1999  37737  172006362
#> 4 Brazil        2000  80488  174504898
#> 5 China         1999 212258  1272915272
#> 6 China         2000 213766  1280428583
table2
```

```

#> # A tibble: 12 × 4
#>   country      year  type     count
#>   <chr>        <dbl> <chr>     <dbl>
#> 1 Afghanistan  1999  cases      745
#> 2 Afghanistan  1999  population  19987071
#> 3 Afghanistan  2000  cases      2666
#> 4 Afghanistan  2000  population  20595360
#> 5 Brazil       1999  cases      37737
#> 6 Brazil       1999  population  172006362
#> # ... with 6 more rows
table3

#> # A tibble: 6 × 3
#>   country      year  rate
#>   <chr>        <dbl> <chr>
#> 1 Afghanistan  1999  745/19987071
#> 2 Afghanistan  2000  2666/20595360
#> 3 Brazil       1999  37737/172006362
#> 4 Brazil       2000  80488/174504898
#> 5 China        1999  212258/1272915272
#> 6 China        2000  213766/1280428583

# Spread across two tibbles
table4a # cases
#> # A tibble: 3 × 3
#>   country    `1999` `2000`
#>   <chr>        <dbl>  <dbl>
#> 1 Afghanistan  745    2666
#> 2 Brazil       37737   80488
#> 3 China        212258  213766

table4b # population
#> # A tibble: 3 × 3
#>   country    `1999`    `2000`
#>   <chr>        <dbl>    <dbl>
#> 1 Afghanistan 19987071  20595360
#> 2 Brazil      172006362  174504898
#> 3 China       1272915272 1280428583

```

These are all representations of the same underlying data, but they are not equally easy to use. One of them, `table1`, will be much easier to work with inside the tidyverse because it's tidy.

There are three interrelated rules that make a dataset tidy:

1. Each variable is a column; each column is a variable.
2. Each observation is a row; each row is an observation.
3. Each value is a cell; each cell is a single value.

Figure 6.1 shows the rules visually.

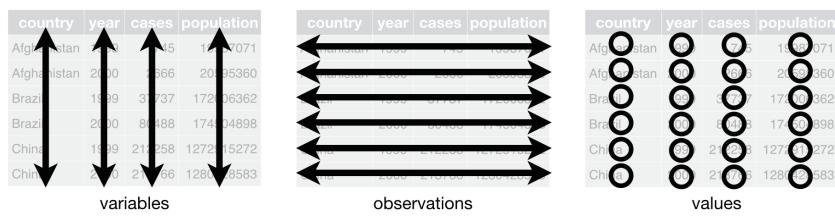

Figure 6.1: The following three rules make a dataset tidy: variables are columns, observations are rows, and values are cells.

Why ensure that your data is tidy? There are two main advantages:

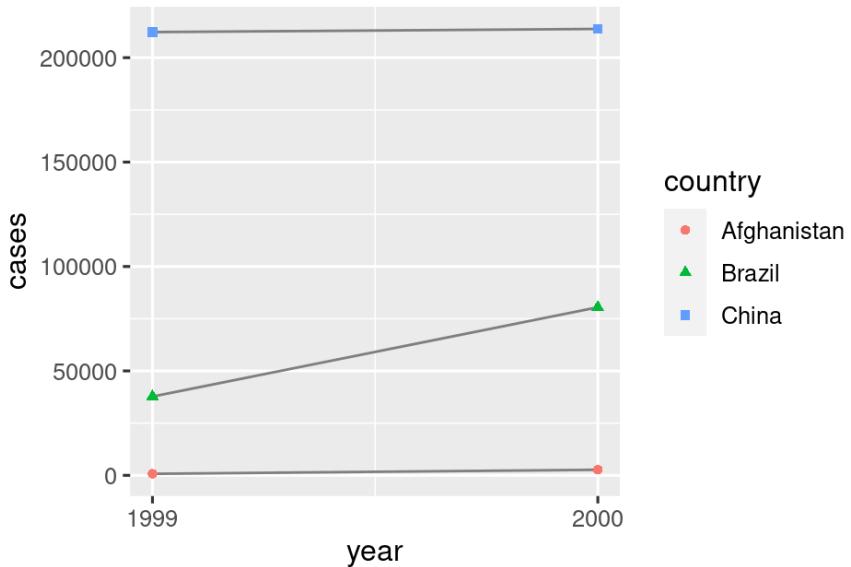

1. There's a general advantage to picking one consistent way of storing data. If you have a consistent data structure, it's easier to learn the tools that work with it because they have an underlying uniformity.
2. There's a specific advantage to placing variables in columns because it allows R's vectorized nature to shine. As you learned in [Section 4.3.1](#) and [Section 4.4.2](#), most built-in R functions work with vectors of values. That makes transforming tidy data feel particularly natural.

dplyr, ggplot2, and all the other packages in the tidyverse are designed to work with tidy data. Here are a few small examples showing how you might work with `table1`.

```
# Compute rate per 10,000
table1 |>
  mutate(
    rate = cases / population * 10000
  )
#> # A tibble: 6 × 5
#>   country      year  cases population   rate
#>   <chr>        <dbl>  <dbl>       <dbl> <dbl>
#> 1 Afghanistan  1999     745  19987071 0.373
#> 2 Afghanistan  2000    2666  20595360 1.29
#> 3 Brazil        1999   37737 172006362 2.19
#> 4 Brazil        2000   80488 174504898 4.61
#> 5 China          1999  212258 1272915272 1.67
#> 6 China          2000  213766 1280428583 1.67

# Compute cases per year
table1 |>
  count(year, wt = cases)
#> # A tibble: 2 × 2
#>   year      n
#>   <dbl>  <dbl>
#> 1 1999  250740
#> 2 2000  296920

# Visualise changes over time
ggplot(table1, aes(x = year, y = cases)) +
  geom_line(aes(group = country), color = "grey50") +
  geom_point(aes(color = country, shape = country)) +
  scale_x_continuous(breaks = c(1999, 2000))
```

6.2.1 Exercises

1. Using prose, describe how the variables and observations are organised in each of the sample tables.
2. Sketch out the process you'd use to calculate the `rate` for `table2` and `table4a + table4b`. You will need to perform four operations:
 - a. Extract the number of TB cases per country per year.
 - b. Extract the matching population per country per year.
 - c. Divide cases by population, and multiply by 10000.
 - d. Store back in the appropriate place.

You haven't yet learned all the functions you'd need to actually perform these operations, but you should still be able to think through the transformations you'd need.

3. Recreate the plot showing change in cases over time using `table2` instead of `table1`. What do you need to do first?

6.3 Pivoting

The principles of tidy data might seem so obvious that you wonder if you'll ever encounter a dataset that isn't tidy. Unfortunately, however, most real data is untidy. There are two main reasons:

1. Data is often organised to facilitate some goal other than analysis.
For example, it's common for data to be structured to make data entry, not analysis, easy.
2. Most people aren't familiar with the principles of tidy data, and it's hard to derive them yourself unless you spend a lot of time working with data.

This means that most real analyses will require at least a little tidying. You'll begin by figuring out what the underlying variables and observations are. Sometimes this is easy; other times you'll need to consult with the people who originally generated the data. Next, you'll **pivot** your data into a tidy form, with variables in the columns and observations in the rows.

`tidyverse` provides two functions for pivoting data: `pivot_longer()`, which makes datasets **longer** by increasing rows and reducing columns, and `pivot_wider()` which makes datasets **wider** by increasing columns and reducing rows. The following sections work through the use of `pivot_longer()` and `pivot_wider()` to tackle a wide range of realistic datasets. These examples are drawn from `vignette("pivot", package = "tidyverse")`, which you should check out if you want to see more variations and more challenging problems.

Let's dive in.

6.3.1 Data in column names

The `billboard` dataset records the billboard rank of songs in the year 2000:

```
billboard
#> # A tibble: 317 × 79
#>   artist      track date.entered¹   wk1    wk2    wk3    wk4
#>   <chr>       <chr>  <date>        <dbl>   <dbl>   <dbl>   <dbl>
#> 1 2 Pac       Baby... 2000-02-26     87     82     72     77
#> 2 2Ge+her     The ... 2000-09-02     91     87     92     NA
#> 3 3 Doors D... Kryp... 2000-04-08     81     70     68     67
#> 4 3 Doors D... Loser  2000-10-21     76     76     72     69
#> 5 504 Boyz    Wobb... 2000-04-15     57     34     25     17
#> 6 98^0        Give... 2000-08-19     51     39     34     26
#> # ... with 311 more rows, 68 more variables: wk9 <dbl>,
#> #   wk11 <dbl>, wk12 <dbl>, wk13 <dbl>, wk14 <dbl>, w
#> #   wk17 <dbl>, wk18 <dbl>, wk19 <dbl>, wk20 <dbl>, w
#> #   wk23 <dbl>, wk24 <dbl>, wk25 <dbl>, wk26 <dbl>, w
#> #   wk29 <dbl>, wk30 <dbl>, wk31 <dbl>, wk32 <dbl>, w
#> #   wk35 <dbl>, wk36 <dbl>, wk37 <dbl>, wk38 <dbl>, w
#> #   wk41 <dbl>, wk42 <dbl>, wk43 <dbl>, wk44 <dbl>, w
```

In this dataset, each observation is a song. The first three columns (`artist`, `track` and `date.entered`) are variables that describe the song. Then we have 76 columns (`wk1`-`wk76`) that describe the rank of the song in each week. Here, the column names are one variable (the `week`) and the cell values are another (the `rank`).

To tidy this data, we'll use `pivot_longer()`. After the data, there are three key arguments:

- `cols` specifies which columns need to be pivoted, i.e. which columns aren't variables. This argument uses the same syntax as `select()` so here we could use `!c(artist, track, date.entered)` or `starts_with("wk")`.
- `names_to` names the variable stored in the column names, here "week".
- `values_to` names the variable stored in the cell values, here "rank".

That gives the following call:

```
billboard |>
  pivot_longer(
    cols = starts_with("wk"),
    names_to = "week",
    values_to = "rank"
  )
#> # A tibble: 24,092 × 5
#>   artist track           date.entered week
#>   <chr>  <chr>          <date>       <chr>
#> 1 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk1
#> 2 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk2
#> 3 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk3
#> 4 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk4
#> 5 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk5

#> # ... with 24,082 more rows
```

What happens if a song is in the top 100 for less than 76 weeks? Take 2 Pac's "Baby Don't Cry", for example. The above output suggests that it

was only the top 100 for 7 weeks, and all the remaining weeks are filled in with missing values. These `NA`s don't really represent unknown observations; they're forced to exist by the structure of the dataset¹, so we can ask `pivot_longer()` to get rid of them by setting `values_drop_na = TRUE`:

```
billboard |>
  pivot_longer(
    cols = starts_with("wk"),
    names_to = "week",
    values_to = "rank",
    values_drop_na = TRUE
  )
#> # A tibble: 5,307 × 5
#>   artist track           date.entered week
#>   <chr>  <chr>          <date>       <chr> 
#> 1 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk1  
#> 2 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk2  
#> 3 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk3  
#> 4 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk4  
#> 5 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk5  
#> 6 2 Pac Baby Don't Cry (Keep... 2000-02-26 wk6  
#> # ... with 5,301 more rows
```

You might also wonder what happens if a song is in the top 100 for more than 76 weeks? We can't tell from this data, but you might guess that additional columns `wk77`, `wk78`, ... would be added to the dataset.

This data is now tidy, but we could make future computation a bit easier by converting `week` into a number using `mutate()` and `readr::parse_number()`. `parse_number()` is a handy function that will extract the first number from a string, ignoring all other text.

```
billboard_tidy <- billboard |>
  pivot_longer(
    cols = starts_with("wk"),
    names_to = "week",
    values_to = "rank",
    values_drop_na = TRUE
  ) |>
  mutate(
    week = parse_number(week)
  )
billboard_tidy
#> # A tibble: 5,307 × 5
#>   artist track           date.entered  week
#>   <chr>  <chr>          <date>        <dbl> <
#> 1 2 Pac Baby Don't Cry (Keep... 2000-02-26     1
#> 2 2 Pac Baby Don't Cry (Keep... 2000-02-26     2
#> 3 2 Pac Baby Don't Cry (Keep... 2000-02-26     3
#> 4 2 Pac Baby Don't Cry (Keep... 2000-02-26     4
#> 5 2 Pac Baby Don't Cry (Keep... 2000-02-26     5
#> 6 2 Pac Baby Don't Cry (Keep... 2000-02-26     6
#> # ... with 5,301 more rows
```

Now we're in a good position to look at how song ranks vary over time by drawing a plot. The code is shown below and the result is [Figure 6.2](#).

```
billboard_tidy |>
  ggplot(aes(x = week, y = rank, group = track)) +
  geom_line(alpha = 1/3) +
  scale_y_reverse()
```

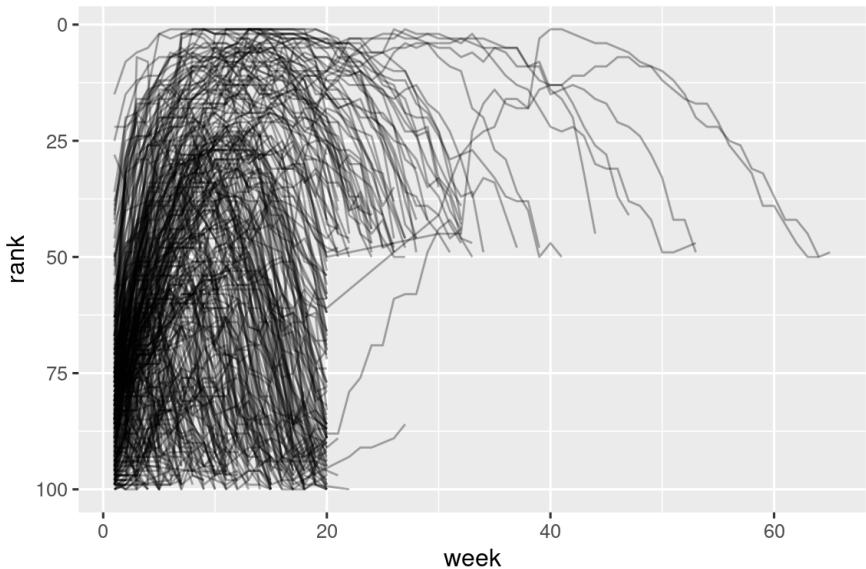

Figure 6.2: A line plot showing how the rank of a song changes over time.

6.3.2 How does pivoting work?

Now that you've seen what pivoting can do for you, it's worth taking a little time to gain some intuition about what it does to the data. Let's start with a very simple dataset to make it easier to see what's happening:

```
df <- tribble(  
  ~var, ~col1, ~col2,  
  "A",     1,     2,  
  "B",     3,     4,  
  "C",     5,     6  
)
```

Here we'll say there are three variables: `var` (already in a variable), `name` (the column names in the column names), and `value` (the cell values). So we can tidy it with:

```

df |>
  pivot_longer(
    cols = col1:col2,
    names_to = "names",
    values_to = "values"
  )
#> # A tibble: 6 × 3
#>   var     names values
#>   <chr> <chr>  <dbl>
#> 1 A       col1      1
#> 2 A       col2      2
#> 3 B       col1      3
#> 4 B       col2      4
#> 5 C       col1      5
#> 6 C       col2      6

```

How does this transformation take place? It's easier to see if we take it component by component. Columns that are already variables need to be repeated, once for each column in `cols`, as shown in [Figure 6.3](#).

var	col1	col2
A	1	2
B	3	4
C	5	6

var	name	value
A	col1	1
A	col2	2
B	col1	3
B	col2	4
C	col1	5
C	col2	6

Figure 6.3: Columns that are already variables need to be repeated, once for each column that is pivotted.

The column names become values in a new variable, whose name is given by `names_to`, as shown in [Figure 6.4](#). They need to be repeated once for each row in the original dataset.

The diagram illustrates the process of pivoting a dataset. On the left, a small table shows three rows (A, B, C) with two columns (col1 and col2). An arrow points from this table to a larger, more detailed table on the right. The right table has three columns: **var**, **name**, and **value**. It contains six rows, corresponding to the three rows of the original table and their two columns. The first two rows (A) have **name** values of "col1" and "col2" respectively, with **value** 1 and 2. The next two rows (B) have **name** values of "col1" and "col2" with **value** 3 and 4. The last two rows (C) have **name** values of "col1" and "col2" with **value** 5 and 6. The **var** column is present in both tables but serves different purposes: it is a primary key in the long-form table, while in the pivot table it indicates the group (A, B, or C).

var	col1	col2
A	1	2
B	3	4
C	5	6

→

var	name	value
A	col1	1
A	col2	2
B	col1	3
B	col2	4
C	col1	5
C	col2	6

Figure 6.4: The column names of pivoted columns become a new column.

The cell values also become values in a new variable, with a name given by `values_to`. They are unwound row by row. [Figure 6.5](#) illustrates the process.

The diagram illustrates a data transformation. On the left, there is a wide table with three columns: 'var', 'col1', and 'col2'. The rows are labeled A, B, and C. The values are: row A has col1=1 and col2=2; row B has col1=3 and col2=4; row C has col1=5 and col2=6. The colors of the cells are: var=black, col1=blue, col2=green (row A), col1=orange, col2=yellow (row B), col1=black, col2=black (row C). An arrow points from this table to a long table on the right. The long table has three columns: 'var', 'name', and 'value'. It contains six rows, corresponding to the six cells in the original table. The 'name' column indicates whether the value belongs to 'col1' or 'col2'. The 'value' column contains the numerical values. The colors of the cells in the long table are: var=black, name=black, value=blue (row 1), name=black, value=green (row 2), name=black, value=orange (row 3), name=black, value=yellow (row 4), name=black, value=black (row 5), name=black, value=black (row 6).

var	col1	col2
A	1	2
B	3	4
C	5	6

var	name	value
A	col1	1
A	col2	2
B	col1	3
B	col2	4
C	col1	5
C	col2	6

Figure 6.5: The number of values is preserved (not repeated), but unwound row-by-row.

6.3.3 Many variables in column names

A more challenging situation occurs when you have multiple variables crammed into the column names. For example, take the `who2` dataset:

```
who2
#> # A tibble: 7,240 × 58
#>   country      year sp_m_014 sp_m_1...¹ sp_m_...² sp_m_...³
#>   <chr>       <dbl>    <dbl>    <dbl>    <dbl>    <dbl>
#> 1 Afghanistan 1980      NA      NA      NA      NA
#> 2 Afghanistan 1981      NA      NA      NA      NA
#> 3 Afghanistan 1982      NA      NA      NA      NA
#> 4 Afghanistan 1983      NA      NA      NA      NA
#> 5 Afghanistan 1984      NA      NA      NA      NA
#> 6 Afghanistan 1985      NA      NA      NA      NA
#> # ... with 7,234 more rows, 49 more variables: sp_f_014
#> #   sp_f_1524 <dbl>, sp_f_2534 <dbl>, sp_f_3544 <dbl>
#> #   sp_f_5564 <dbl>, sp_f_65 <dbl>, sn_m_014 <dbl>, s
#> #   sn_m_2534 <dbl>, sn_m_3544 <dbl>, sn_m_4554 <dbl>
#> #   sn_m_65 <dbl>, sn_f_014 <dbl>, sn_f_1524 <dbl>, s
```

```
#> #   sn_f_3544 <dbl>, sn_f_4554 <dbl>, sn_f_5564 <dbl>
#> #   ep_m_014 <dbl>, ep_m_1524 <dbl>, ep_m_2534 <dbl>,
```

This dataset records information about tuberculosis data collected by the WHO. There are two columns that are already variables and are easy to interpret: `country` and `year`. They are followed by 56 columns like `sp_m_014`, `ep_m_4554`, and `rel_m_3544`. If you stare at these columns for long enough, you'll notice there's a pattern. Each column name is made up of three pieces separated by `_`. The first piece, `sp / rel / ep`, describes the method used for the `diagnosis`, the second piece, `m / f` is the `gender`, and the third piece, `014 / 1524 / 2535 / 3544 / 4554 / 65` is the `age range`.

So in this case we have six variables: two variables are already columns, three variables are contained in the column name, and one variable is in the cell name. This requires two changes to our call to `pivot_longer()`: `names_to` gets a vector of column names and `names_sep` describes how to split the variable name up into pieces:

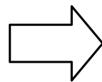

```
who2 |>
  pivot_longer(
    cols = !(country:year),
    names_to = c("diagnosis", "gender", "age"),
    names_sep = "_",
    values_to = "count"
  )
#> # A tibble: 405,440 × 6
#>   country      year diagnosis gender age   count
#>   <chr>       <dbl> <chr>     <chr>  <chr> <dbl>
#> 1 Afghanistan  1980 sp        m      014     NA
#> 2 Afghanistan  1980 sp        m      1524    NA
#> 3 Afghanistan  1980 sp        m      2534    NA
#> 4 Afghanistan  1980 sp        m      3544    NA
#> 5 Afghanistan  1980 sp        m      4554    NA
```

```
#> 6 Afghanistan 1980 sp m 5564 NA  
#> # ... with 405,434 more rows
```

An alternative to `names_sep` is `names_pattern`, which you can use to extract variables from more complicated naming scenarios, once you've learned about regular expressions in [Chapter 17](#).

Conceptually, this is only a minor variation on the simpler case you've already seen. [Figure 6.6](#) shows the basic idea: now, instead of the column names pivoting into a single column, they pivot into multiple columns. You can imagine this happening in two steps (first pivoting and then separating) but under the hood it happens in a single step because that gives better performance.

var	x_1	y_2
A	1	2
B	3	4
C	5	6

var	name	number	value
A	x	1	1
A	y	2	2
B	x	1	3
B	y	2	4
C	x	1	5
C	y	2	6

Figure 6.6: Pivotting with many variables in the column names means that each column name now fills in values in multiple output columns.

6.3.4 Data and variable names in the column headers

The next step up in complexity is when the column names include a mix of variable values and variable names. For example, take the `household` dataset:

```
household  
#> # A tibble: 5 × 5
```

```

#>   family dob_child1 dob_child2 name_child1 name_child2
#>   <int> <date>     <date>     <chr>      <chr>
#> 1     1 1998-11-26 2000-01-29 Susan       Jose
#> 2     2 1996-06-22 NA          Mark        <NA>
#> 3     3 2002-07-11 2004-04-05 Sam         Seth
#> 4     4 2004-10-10 2009-08-27 Craig      Khai
#> 5     5 2000-12-05 2005-02-28 Parker    Gracie

```

This dataset contains data about five families, with the names and dates of birth of up to two children. The new challenge in this dataset is that the column names contain the names of two variables (`dob`, `name`) and the values of another (`child`, with values 1 and 2). To solve this problem we again need to supply a vector to `names_to` but this time we use the special "`.value`" sentinel. This overrides the usual `values_to` argument to use the first component of the pivoted column name as a variable name in the output.

```

household |>
  pivot_longer(
    cols = !family,
    names_to = c(".value", "child"),
    names_sep = "_",
    values_drop_na = TRUE
  ) |>
  mutate(
    child = parse_number(child)
  )
#> # A tibble: 9 × 4
#>   family child dob           name
#>   <int> <dbl> <date>       <chr>
#> 1     1     1 1998-11-26 Susan
#> 2     1     2 2000-01-29 Jose
#> 3     2     1 1996-06-22 Mark
#> 4     3     1 2002-07-11 Sam
#> 5     3     2 2004-04-05 Seth

```

```
#> 6      4      1 2004-10-10 Craig
```

```
#> # ... with 3 more rows
```

We again use `values_drop_na = TRUE`, since the shape of the input forces the creation of explicit missing variables (e.g. for families with only one child), and `parse_number()` to convert (e.g.) `child1` into 1.

Figure 6.7 illustrates the basic idea with a simpler example. When you use `".value"` in `names_to`, the column names in the input contribute to both values and variable names in the output.

The diagram illustrates the pivoting process. On the left, a wide input table has columns labeled `var`, `x_1`, `x_2`, `y_1`, and `y_2`. The rows are labeled `A` and `B`, with values 1, 2, 3, 4 for row A and 5, 6, 7, 8 for row B. An arrow points to the right, leading to a long output table. This output table has columns `var`, `x`, `y`, and `id`. The rows are labeled `A`, `A`, `B`, `B`. The `x` column contains 1, 2, 5, 6. The `y` column contains 3, 4, 7, 8. The `id` column contains 1, 2, 1, 2, corresponding to the original `y_1` and `y_2` values.

var	x_1	x_2	y_1	y_2
A	1	2	3	4
B	5	6	7	8

→

var	x	y	id
A	1	3	1
A	2	4	2
B	5	7	1
B	6	8	2

Figure 6.7: Pivoting with `names_to = c(".value", "id")` splits the column names into two components: the first part determines the output column name (`x` or `y`), and the second part determines the value of the `id` column.

6.3.5 Widening data

So far we've used `pivot_longer()` to solve the common class of problems where values have ended up in column names. Next we'll pivot (HA HA) to `pivot_wider()`, which helps when one observation is spread across multiple rows. This seems to arise less commonly in the wild, but it does seem to crop up a lot when dealing with governmental data.

We'll start by looking at `cms_patient_experience`, a dataset from the Centers of Medicare and Medicaid services that collects data about

patient experiences:

```
cms_patient_experience
#> # A tibble: 500 × 5
#>   org_pac_id org_nm               measure_cd
#>   <chr>      <chr>
#> 1 0446157747 USC CARE MEDICAL GROUP INC CAHPS_GRP_1
#> 2 0446157747 USC CARE MEDICAL GROUP INC CAHPS_GRP_2
#> 3 0446157747 USC CARE MEDICAL GROUP INC CAHPS_GRP_3
#> 4 0446157747 USC CARE MEDICAL GROUP INC CAHPS_GRP_5
#> 5 0446157747 USC CARE MEDICAL GROUP INC CAHPS_GRP_8
#> 6 0446157747 USC CARE MEDICAL GROUP INC CAHPS_GRP_12
#> # ... with 494 more rows, and abbreviated variable name
```

An observation is an organisation, but each organisation is spread across six rows, with one row for each variable, or measure. We can see the complete set of values for `measure_cd` and `measure_title` by using `distinct()`:

```
cms_patient_experience |>
  distinct(measure_cd, measure_title)
#> # A tibble: 6 × 2
#>   measure_cd    measure_title
#>   <chr>        <chr>
#> 1 CAHPS_GRP_1  CAHPS for MIPS SSM: Getting Timely Car
#> 2 CAHPS_GRP_2  CAHPS for MIPS SSM: How Well Providers
#> 3 CAHPS_GRP_3  CAHPS for MIPS SSM: Patient's Rating o
#> 4 CAHPS_GRP_5  CAHPS for MIPS SSM: Health Promotion a
#> 5 CAHPS_GRP_8  CAHPS for MIPS SSM: Courteous and Help
#> 6 CAHPS_GRP_12 CAHPS for MIPS SSM: Stewardship of Pat
```

Neither of these columns will make particularly great variable names: `measure_cd` doesn't hint at the meaning of the variable and `measure_title` is a long sentence containing spaces. We'll use `measure_cd` for now, but in a real analysis you might want to create your own variable names that are both short and meaningful.

`pivot_wider()` has the opposite interface to `pivot_longer()`: we need to provide the existing columns that define the values (`values_from`) and the column name (`names_from`):

```
cms_patient_experience |>
  pivot_wider(
    names_from = measure_cd,
    values_from = prf_rate
  )
#> # A tibble: 500 × 9
#>   org_pac_id org_nm   measu...¹ CAHPS...² CAHPS...³ CAHPS...⁴
#>   <chr>      <chr>     <chr>      <dbl>      <dbl>      <dbl>
#> 1 0446157747 USC CAR... CAHPS ...     63        NA        NA
#> 2 0446157747 USC CAR... CAHPS ...     NA        87        NA
#> 3 0446157747 USC CAR... CAHPS ...     NA        NA        86
#> 4 0446157747 USC CAR... CAHPS ...     NA        NA        NA
#> 5 0446157747 USC CAR... CAHPS ...     NA        NA        NA
#> 6 0446157747 USC CAR... CAHPS ...     NA        NA        NA
#> # ... with 494 more rows, and abbreviated variable name
#> #   ²CAHPS_GRP_1, ³CAHPS_GRP_2, ⁴CAHPS_GRP_3, ⁵CAHPS_
#> #   ⁷CAHPS_GRP_12
```

The output doesn't look quite right; we still seem to have multiple rows for each organization. That's because, by default, `pivot_wider()` will attempt to preserve all the existing columns including `measure_title` which has six distinct observations for each organisations. To fix this

problem we need to tell `pivot_wider()` which columns identify each row; in this case those are the variables starting with "org":

```
cms_patient_experience |>
  pivot_wider(
    id_cols = starts_with("org"),
    names_from = measure_cd,
    values_from = prf_rate
  )
#> # A tibble: 95 × 8
#>   org_pac_id org_nm      CAHPS...¹ CAHPS...² CAHPS...³
#>   <chr>     <chr>      <dbl>      <dbl>      <dbl>
#> 1 0446157747 USC CARE MEDICA... 63          87          86
#> 2 0446162697 ASSOCIATION OF ... 59          85          83
#> 3 0547164295 BEAVER MEDICAL ... 49          NA          75
#> 4 0749333730 CAPE PHYSICIANS... 67          84          85
#> 5 0840104360 ALLIANCE PHYSIC... 66          87          87
#> 6 0840109864 REX HOSPITAL INC 73          87          84
#> # ... with 89 more rows, and abbreviated variable names
#> #   ²CAHPS_GRP_2, ³CAHPS_GRP_3, ⁴CAHPS_GRP_5, ⁵CAHPS_
```

This gives us the output that we're looking for.

6.3.6 How does `pivot_wider()` work?

To understand how `pivot_wider()` works, let's again start with a very simple dataset:

```
df <- tribble(
  ~id, ~name, ~value,
  "A", "x", 1,
  "B", "y", 2,
  "B", "x", 3,
  "A", "y", 4,
```

```
"A", "z", 5,  
)
```

We'll take the values from the `value` column and the names from the `name` column:

```
df |>  
  pivot_wider(  
    names_from = name,  
    values_from = value  
)  
#> # A tibble: 2 × 4  
#>   id      x     y     z  
#>   <chr> <dbl> <dbl> <dbl>  
#> 1 A         1     4     5  
#> 2 B         3     2    NA
```

The connection between the position of the row in the input and the cell in the output is weaker than in `pivot_longer()` because the rows and columns in the output are primarily determined by the values of variables, not their locations.

To begin the process `pivot_wider()` needs to first figure out what will go in the rows and columns. Finding the column names is easy: it's just the values of `name`.

```
df |>  
  distinct(name)  
#> # A tibble: 3 × 1  
#>   name  
#>   <chr>  
#> 1 x  
#> 2 y  
#> 3 z
```

By default, the rows in the output are formed by all the variables that aren't going into the names or values. These are called the `id_cols`.

```
df |>
  select(-name, -value) |>
  distinct()
#> # A tibble: 2 × 1
#>   id
#>   <chr>
#> 1 A
#> 2 B
```

`pivot_wider()` then combines these results to generate an empty data frame:

```
df |>
  select(-name, -value) |>
  distinct() |>
  mutate(x = NA, y = NA, z = NA)
#> # A tibble: 2 × 4
#>   id     x     y     z
#>   <chr> <lgl> <lgl> <lgl>
#> 1 A      NA    NA    NA
#> 2 B      NA    NA    NA
```

It then fills in all the missing values using the data in the input. In this case, not every cell in the output has corresponding value in the input as there's no entry for id "B" and name "z", so that cell remains missing. We'll come back to this idea that `pivot_wider()` can "make" missing values in [Chapter 20](#).

You might also wonder what happens if there are multiple rows in the input that correspond to one cell in the output. The example below has two rows that correspond to id "A" and name "x":

```
df <- tribble(  
  ~id, ~name, ~value,  
  "A", "x", 1,  
  "A", "x", 2,  
  "A", "y", 3,  
  "B", "x", 4,  
  "B", "y", 5,  
)
```

If we attempt to pivot this we get an output that contains list-columns, which you'll learn more about in [Chapter 25](#):

```
df |> pivot_wider(  
  names_from = name,  
  values_from = value  
)  
#> Warning: Values from `value` are not uniquely identified  
#> by list-cols.  
#> • Use `values_fn = list` to suppress this warning.  
#> • Use `values_fn = {summary_fun}` to summarise duplicates  
#> • Use the following dplyr code to identify duplicates  
#>   {data} %>%  
#>   dplyr::group_by(id, name) %>%  
#>   dplyr::summarise(n = dplyr::n(), .groups = "drop")  
#>   dplyr::filter(n > 1L)  
#> # A tibble: 2 × 3  
#>   id     x         y  
#>   <chr> <list>    <list>  
#> 1 A      <dbl [2]> <dbl [1]>  
#> 2 B      <dbl [1]> <dbl [1]>
```

Since you don't know how to work with this sort of data yet, you'll want to follow the hint in the warning to figure out where the problem is:

```
df |>
  group_by(id, name) |>
  summarize(n = n(), .groups = "drop") |>
  filter(n > 1L)
#> # A tibble: 1 × 3
#>   id     name     n
#>   <chr> <chr> <int>
#> 1 A      x        2
```

It's then up to you to figure out what's gone wrong with your data and either repair the underlying damage or use your grouping and summarizing skills to ensure that each combination of row and column values only has a single row.

6.4 Untidy data

While `pivot_wider()` is occasionally useful for making tidy data, its real strength is making **untidy** data. While that sounds like a bad thing, untidy isn't a pejorative term: there are many untidy data structures that are extremely useful. Tidy data is a great starting point for most analyses but it's not the only data format you'll ever need.

The following sections will show a few examples of `pivot_wider()` making usefully untidy data for presenting data to other humans, for input to multivariate statistics algorithms, and for pragmatically solving data manipulation challenges.

6.4.1 Presenting data to humans

As you've seen, `dplyr::count()` produces tidy data: it makes one row for each group, with one column for each grouping variable, and one column for the number of observations.

```
diamonds |>
  count(clarity, color)
#> # A tibble: 56 × 3
#>   clarity color     n
#>   <ord>    <ord> <int>
#> 1 I1       D     42
#> 2 I1       E    102
#> 3 I1       F    143
#> 4 I1       G    150
#> 5 I1       H    162
#> 6 I1       I     92
#> # ... with 50 more rows
```

This is easy to visualize or summarize further, but it's not the most compact form for display. You can use `pivot_wider()` to create a form more suitable for display to other humans:

```
diamonds |>
  count(clarity, color) |>
  pivot_wider(
    names_from = color,
    values_from = n
  )
#> # A tibble: 8 × 8
#>   clarity      D      E      F      G      H      I      J
#>   <ord>    <int> <int> <int> <int> <int> <int> <int>
#> 1 I1        42    102    143    150    162    92    50
#> 2 SI2      1370   1713   1609   1548   1563   912   479
#> 3 SI1      2083   2426   2131   1976   2275   1424   750
#> 4 VS2      1697   2470   2201   2347   1643   1169   731
#> 5 VS1       705   1281   1364   2148   1169   962    542
#> 6 VVS2      553    991    975   1443    608    365   131
#> # ... with 2 more rows
```

This display also makes it easy to compare in two directions, horizontally and vertically, much like `facet_grid()`.

`pivot_wider()` can be great for quickly sketching out a table. But for real presentation tables, we highly suggest learning a package like `gt`. `gt` is similar to `ggplot2` in that it provides an extremely powerful grammar for laying out tables. It takes some work to learn but the payoff is the ability to make just about any table you can imagine.

6.4.2 Multivariate statistics

Most classical multivariate statistical methods (like dimension reduction and clustering) require your data in matrix form, where each column is a time point, or a location, or a gene, or a species, but definitely not a variable. Sometimes these formats have substantial performance or space advantages, or sometimes they're just necessary to get closer to the underlying matrix mathematics.

We're not going to cover these statistical methods here, but it is useful to know how to get your data into the form that they need. For example, let's imagine you wanted to cluster the gapminder data to find countries that had similar progression of `gdpPercap` over time. To do this, we need one row for each country and one column for each year:

```
library(gapminder)

col_year <- gapminder |>
  mutate(gdpPercap = log10(gdpPercap)) |>
  pivot_wider(
    id_cols = country,
    names_from = year,
    values_from = gdpPercap
  )
col_year
#> # A tibble: 142 × 13
```

```

#>   country    `1952` `1957` `1962` `1967` `1972` `197
#>   <fct>     <dbl>  <dbl>  <dbl>  <dbl>  <dbl>  <dt
#> 1 Afghanistan 2.89   2.91   2.93   2.92   2.87   2.
#> 2 Albania      3.20   3.29   3.36   3.44   3.52   3.
#> 3 Algeria       3.39   3.48   3.41   3.51   3.62   3.
#> 4 Angola        3.55   3.58   3.63   3.74   3.74   3.
#> 5 Argentina     3.77   3.84   3.85   3.91   3.98   4.
#> 6 Australia     4.00   4.04   4.09   4.16   4.23   4.
#> # ... with 136 more rows, and 3 more variables: `1997` 
#> #   `2007` <dbl>

```

`pivot_wider()` produces a tibble where each row is labelled by the `country` variable. But most classic statistical algorithms don't want the identifier as an explicit variable; they want as a **row name**. We can turn the `country` variable into row names with `column_to_rownames()`:

```

col_year <- col_year |>
  column_to_rownames("country")

head(col_year)
#>           1952      1957      1962      1967      1
#> Afghanistan 2.891786 2.914265 2.931000 2.922309 2.869
#> Albania      3.204407 3.288313 3.364155 3.440940 3.520
#> Algeria       3.388990 3.479140 3.406679 3.511481 3.621
#> Angola        3.546618 3.582965 3.630354 3.742157 3.738
#> Argentina     3.771684 3.836125 3.853282 3.905955 3.975
#> Australia     4.001716 4.039400 4.086973 4.162150 4.225
#>           1987      1992      1997      2002      2
#> Afghanistan 2.930641 2.812473 2.803007 2.861376 2.988
#> Albania      3.572748 3.397495 3.504206 3.663155 3.773
#> Algeria       3.754452 3.700982 3.680996 3.723295 3.794
#> Angola        3.385644 3.419600 3.357390 3.442995 3.680

```

```
#> Argentina    3.960931 3.968876 4.040099 3.944366 4.106  
#> Australia    4.340224 4.369675 4.431331 4.486965 4.537
```

This makes a data frame, because tibbles don't support row names².

We're now ready to cluster with (e.g.) `kmeans()`:

```
cluster <- stats::kmeans(col_year, centers = 6)
```

Extracting the data out of this object into a form you can work with is a challenge you'll need to come back to later in the book, once you've learned more about lists. But for now, you can get the clustering membership out with this code:

```
cluster_id <- cluster$cluster |>  
  enframe() |>  
  rename(country = name, cluster_id = value)  
cluster_id  
#> # A tibble: 142 × 2  
#>   country      cluster_id  
#>   <chr>          <int>  
#> 1 Afghanistan      4  
#> 2 Albania            2  
#> 3 Algeria             6  
#> 4 Angola              2  
#> 5 Argentina           5  
#> 6 Australia            1  
#> # ... with 136 more rows
```

You could then combine this back with the original data using one of the joins you'll learn about in [Chapter 21](#).

```
gapminder |> left_join(cluster_id)  
#> Joining with `by = join_by(country)`
```

```
#> # A tibble: 1,704 × 7
#>   country     continent   year lifeExp      pop gdpPer
#>   <chr>       <fct>     <int>   <dbl>    <int>    <dbl>
#> 1 Afghanistan Asia        1952    28.8    8425333    7
#> 2 Afghanistan Asia        1957    30.3    9240934    8
#> 3 Afghanistan Asia        1962    32.0    10267083    8
#> 4 Afghanistan Asia        1967    34.0    11537966    8
#> 5 Afghanistan Asia        1972    36.1    13079460    7
#> 6 Afghanistan Asia        1977    38.4    14880372    7
#> # ... with 1,698 more rows
```

6.4.3 Pragmatic computation

Sometimes it's just easier to answer a question using untidy data. For example, if you're interested in just the total number of missing values in `cms_patient_experience`, it's easier to work with the untidy form:

```
cms_patient_experience |>
  group_by(org_pac_id) |>
  summarize(
    n_miss = sum(is.na(prf_rate)),
    n = n(),
  )
#> # A tibble: 95 × 3
#>   org_pac_id   n_miss     n
#>   <chr>       <int> <int>
#> 1 0446157747     0     6
#> 2 0446162697     0     6
#> 3 0547164295     1     6
#> 4 0749333730     0     6
#> 5 0840104360     0     6
#> 6 0840109864     0     6
#> # ... with 89 more rows
```

This is partly a reflection of our definition of tidy data, where we said tidy data has one variable in each column, but we didn't actually define what a variable is (and it's surprisingly hard to do so). It's totally fine to be pragmatic and to say a variable is whatever makes your analysis easiest.

So if you're stuck figuring out how to do some computation, maybe it's time to switch up the organisation of your data. For computations involving a fixed number of values (like computing differences or ratios), it's usually easier if the data is in columns; for those with a variable number of values (like sums or means) it's usually easier in rows. Don't be afraid to untidy, transform, and re-tidy if needed.

Let's explore this idea by looking at `cms_patient_care`, which has a similar structure to `cms_patient_experience`:

```
cms_patient_care
#> # A tibble: 252 × 5
#>   ccn    facility_name    measure_abbr      score type
#>   <chr>  <chr>          <chr>           <dbl> <chr>
#> 1 011500 BAPTIST HOSPICE beliefs_addressed 202   denc
#> 2 011500 BAPTIST HOSPICE beliefs_addressed 100   obse
#> 3 011500 BAPTIST HOSPICE composite_process 202   denc
#> 4 011500 BAPTIST HOSPICE composite_process  88.1 obse
#> 5 011500 BAPTIST HOSPICE dyspnea_treatment 110   denc
#> 6 011500 BAPTIST HOSPICE dyspnea_treatment  99.1 obse
#> # ... with 246 more rows
```

It contains information about 9 measures (`beliefs_addressed`, `composite_process`, `dyspnea_treatment`, ...) on 14 different facilities (identified by `ccn` with a name given by `facility_name`). Compared to `cms_patient_experience`, however, each measurement is recorded in two rows with a `score`, the percentage of patients who

answered yes to the survey question, and a denominator, the number of patients that the question applies to. Depending on what you want to do next, you may find any of the following three structures useful:

- If you want to compute the number of patients that answered yes to the question, you may pivot `type` into the columns:

```
cms_patient_care |>
  pivot_wider(
    names_from = type,
    values_from = score
  ) |>
  mutate(
    numerator = round(observed / 100 * denominator)
  )
#> # A tibble: 126 × 6
#>   ccn      facility_name    measure_abbr      denomi...
#>   <chr>    <chr>          <chr>
#> 1 011500  BAPTIST HOSPICE beliefs_addressed
#> 2 011500  BAPTIST HOSPICE composite_process
#> 3 011500  BAPTIST HOSPICE dyspnea_treatment
#> 4 011500  BAPTIST HOSPICE dyspnea_screening
#> 5 011500  BAPTIST HOSPICE opioid_bowel
#> 6 011500  BAPTIST HOSPICE pain_assessment
#> # ... with 120 more rows
```

- If you want to display the distribution of each metric, you may keep it as is so you could facet by `measure_abbr`.

```
cms_patient_care |>
  filter(type == "observed") |>
  ggplot(aes(x = score)) +
  geom_histogram(binwidth = 2) +
```

```
facet_wrap(vars(measure_abbr))  
#> Warning: Removed 1 rows containing non-finite val
```

- If you want to explore how different metrics are related, you may put the measure names in the columns so you could compare them in scatterplots.

```
cms_patient_care |>  
  filter(type == "observed") |>  
  select(-type) |>  
  pivot_wider(  
    names_from = measure_abbr,  
    values_from = score  
) |>  
  ggplot(aes(x = dyspnea_screening, y = dyspnea_trea  
  geom_point() +  
  coord_equal()
```

6.5 Summary

In this chapter you learned about tidy data: data that has variables in columns and observations in rows. Tidy data makes working in the tidyverse easier, because it's a consistent structure understood by most functions: the main challenge is data from whatever structure you receive it in to a tidy format. To that end, you learn about `pivot_longer()` and `pivot_wider()` which allow you to tidy up many untidy datasets. Of course, tidy data can't solve every problem so we also showed you some places were you might want to deliberately untidy your data into order to present to humans, feed into statistical models, or just pragmatically get shit done. If you particularly enjoyed this chapter and want to learn more about the underlying theory, you

can learn more about the history and theoretical underpinnings in the [Tidy Data](#) paper published in the Journal of Statistical Software.

In the next chapter, we'll pivot back to workflow to discuss the importance of code style, keeping your code "tidy" (ha!) in order to make it easy for you and others to read and understand your code.

1. We'll come back to this idea in [Chapter 20.](#) 
2. tibbles don't use row names because they only work for a subset of important cases: when observations can be identified by a single character vector. 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

i You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

Good coding style is like correct punctuation: you can manage without it, but it surely makes things easier to read. Even as a very new programmer, it's a good idea to work on your code style. Using a consistent style makes it easier for others (including future-you!) to read your work and is particularly important if you need to get help from someone else. This chapter will introduce the most important points of the [tidyverse style guide](#), which is used throughout this book.

Styling your code will feel a bit tedious to start with, but if you practice it, it will soon become second nature. Additionally, there are some great tools to quickly restyle existing code, like the **styler** package by Lorenz Walthert. Once you've installed it with

```
install.packages("styler")
```

, an easy way to use it is via RStudio's **command palette**. The command palette lets you use any built-in RStudio command and many addins provided by packages. Open the palette by pressing Cmd/Ctrl + Shift + P, then type "styler" to see all the shortcuts offered by styler. [Figure 7.1](#) shows the results.

Figure 7.1: RStudio’s command palette makes it easy to access every RStudio command using only the keyboard.

```
library(tidyverse)  
library(nycflights13)
```

7.1 Names

We talked briefly about names in [Section 3.3](#). Remember that variable names (those created by `<-` and those created by `mutate()`) should use only lowercase letters, numbers, and `_`. Use `_` to separate words within a name.

```
# Strive for:  
short_flights <- flights |> filter(air_time < 60)  
  
# Avoid:  
SHORTFLIGHTS <- flights |> filter(air_time < 60)
```

As a general rule of thumb, it’s better to prefer long, descriptive names that are easy to understand rather than concise names that are fast to type. Short names save relatively little time when writing code (especially since autocomplete will help you finish typing them), but it can be time-consuming when you come back to old code and are forced to puzzle out a cryptic abbreviation.

If you have a bunch of names for related things, do your best to be consistent. It's easy for inconsistencies to arise when you forget a previous convention, so don't feel bad if you have to go back and rename things. In general, if you have a bunch of variables that are a variation on a theme, you're better off giving them a common prefix rather than a common suffix because autocomplete works best on the start of a variable.

7.2 Spaces

Put spaces on either side of mathematical operators apart from `^` (i.e. `+`, `-`, `==`, `<`, ...), and around the assignment operator (`<-`).

```
# Strive for
z <- (a + b)^2 / d
```

```
# Avoid
z<-( a + b ) ^ 2/d
```

Don't put spaces inside or outside parentheses for regular function calls. Always put a space after a comma, just like in standard English.

```
# Strive for
mean(x, na.rm = TRUE)
```

```
# Avoid
mean (x ,na.rm=TRUE)
```

It's OK to add extra spaces if it improves alignment. For example, if you're creating multiple variables in `mutate()`, you might want to add spaces so that all the `=` line up. This makes it easier to skim the code.

```
flights |>
  mutate(
    speed      = air_time / distance,
    dep_hour   = dep_time %/% 100,
    dep_minute = dep_time %% 100
  )
```

7.3 Pipes

|> should always have a space before it and should typically be the last thing on a line. This makes it easier to add new steps, rearrange existing steps, modify elements within a step, and get a 50,000 ft view by skimming the verbs on the left-hand side.

```
# Strive for
flights |>
  filter(!is.na(arr_delay), !is.na(tailnum)) |>
  count(dest)

# Avoid
flights |>filter(!is.na(arr_delay), !is.na(tailnum)) |>cou
```

If the function you're piping into has named arguments (like `mutate()` or `summarize()`), put each argument on a new line. If the function doesn't have named arguments (like `select()` or `filter()`), keep everything on one line unless it doesn't fit, in which case you should put each argument on its own line.

```
# Strive for
flights |>
  group_by(tailnum) |>
```

```
summarize(  
  delay = mean(arr_delay, na.rm = TRUE),  
  n = n()  
)  
  
# Avoid  
flights |>  
  group_by(  
    tailnum  
) |>  
  summarize(delay = mean(arr_delay, na.rm = TRUE), n = r
```

After the first step of the pipeline, indent each line by two spaces. If you're putting each argument on its own line, indent by an extra two spaces. Make sure `)` is on its own line, and un-indented to match the horizontal position of the function name.

```
# Strive for  
flights |>  
  group_by(tailnum) |>  
  summarize(  
    delay = mean(arr_delay, na.rm = TRUE),  
    n = n()  
)  
  
# Avoid  
flights |>  
  group_by(tailnum) |>  
  summarize(  
    delay = mean(arr_delay, na.rm = TRUE),  
    n = n()  
)  
  
flights |>  
  group_by(tailnum) |>
```

```
summarize(  
  delay = mean(arr_delay, na.rm = TRUE),  
  n = n()  
)
```

It's OK to shirk some of these rules if your pipeline fits easily on one line. But in our collective experience, it's common for short snippets to grow longer, so you'll usually save time in the long run by starting with all the vertical space you need.

```
# This fits compactly on one line  
df |> mutate(y = x + 1)  
  
# While this takes up 4x as many lines, it's easily exte  
# more variables and more steps in the future  
df |>  
  mutate(  
    y = x + 1  
  )
```

Finally, be wary of writing very long pipes, say longer than 10-15 lines. Try to break them up into smaller sub-tasks, giving each task an informative name. The names will help cue the reader into what's happening and makes it easier to check that intermediate results are as expected. Whenever you can give something an informative name, you should give it an informative name. Don't expect to get it right the first time! This means breaking up long pipelines if there are intermediate states that can get good names.

7.4 ggplot2

The same basic rules that apply to the pipe also apply to ggplot2; just treat `+` the same way as `|>`.

```
flights |>
  group_by(month) |>
  summarize(
    delay = mean(arr_delay, na.rm = TRUE)
  ) |>
  ggplot(aes(x = month, y = delay)) +
  geom_point() +
  geom_line()
```

Again, if you can't fit all of the arguments to a function on to a single line, put each argument on its own line:

```
flights |>
  group_by(dest) |>
  summarize(
    distance = mean(distance),
    speed = mean(air_time / distance, na.rm = TRUE)
  ) |>
  ggplot(aes(x = distance, y = speed)) +
  geom_smooth(
    method = "loess",
    span = 0.5,
    se = FALSE,
    color = "white",
    size = 4
  ) +
  geom_point()
```

7.5 Sectioning comments

As your scripts get longer, you can use **sectioning** comments to break up your file into manageable pieces:

```
# Load data -----
```

```
# Plot data -----
```

RStudio provides a keyboard shortcut to create these headers (Cmd/Ctrl + Shift + R), and will display them in the code navigation drop-down at the bottom-left of the editor, as shown in [Figure 7.2](#).

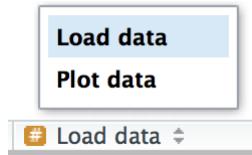

Figure 7.2: After adding sectioning comments to your script, you can easily navigate to them using the code navigation tool in the bottom-left of the script editor.

7.6 Exercises

1. Restyle the following pipelines following the guidelines above.

```
flights|>filter(dest=="IAH")|>group_by(year,month,da
```

```
flights|>filter(carrier=="UA",dest%in%c("IAH","HOU"))
```

7.7 Summary

In this chapter, you've learned the most important principles of code style. These may feel like a set of arbitrary rules to start with (because they are!) but over time, as you write more code, and share code with more people, you'll see how important a consistent style is. And don't forget about the `styler` package: it's a great way to quickly improve the quality of poorly styled code.

So far, we've worked with datasets bundled inside of R packages. This makes it easier to get some practice on pre-prepared data, but obviously your data won't be available in this way. So in the next chapter, you're going to learn how to load data from disk into your R session using the `readr` package.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

8.1 Introduction

Working with data provided by R packages is a great way to learn data science tools, but you want to apply what you've learned to your own data at some point. In this chapter, you'll learn the basics of reading data files into R.

Specifically, this chapter will focus on reading plain-text rectangular files. We'll start with practical advice for handling features like column names, types, and missing data. You will then learn about reading data from multiple files at once and writing data from R to a file. Finally, you'll learn how to handcraft data frames in R.

8.1.1 Prerequisites

In this chapter, you'll learn how to load flat files in R with the **readr** package, which is part of the core tidyverse.

```
library(tidyverse)
```

8.2 Reading data from a file

To begin, we'll focus on the most rectangular data file type: CSV, which is short for comma-separated values. Here is what a simple CSV file looks like. The first row, commonly called the header row, gives the column names, and the following six rows provide the data.

```
#> Student ID,Full Name,favourite.food,mealPlan,AGE  
#> 1,Sunil Huffmann,Strawberry yoghurt,Lunch only,4  
#> 2,Barclay Lynn,French fries,Lunch only,5  
#> 3,Jayendra Lyne,N/A,Breakfast and lunch,7  
#> 4,Leon Rossini,Anchovies,Lunch only,  
#> 5,Chidiegwu Dunkel,Pizza,Breakfast and lunch,five  
#> 6,Güvenç Attila,Ice cream,Lunch only,6
```

Table 8.1 shows a representation of the same data as a table.

Table 8.1: Data from the students.csv file as a table.

Student				
ID	Full Name	favourite.food	mealPlan	AGE
1	Sunil Huffmann	Strawberry yoghurt	Lunch only	4
2	Barclay Lynn	French fries	Lunch only	5
3	Jayendra Lyne	N/A	Breakfast and lunch	7
4	Leon Rossini	Anchovies	Lunch only	NA
5	Chidiegwu Dunkel	Pizza	Breakfast and lunch	five
6	Güvenç Attila	Ice cream	Lunch only	6

We can read this file into R using `read_csv()`. The first argument is the most important: it's the path to the file.

```
students <- read_csv("data/students.csv")
#> Rows: 6 Columns: 5
#> — Column specification —
#> Delimiter: ","
#> chr (4): Full Name, favourite.food, mealPlan, AGE
#> dbl (1): Student ID
#>
#> i Use `spec()` to retrieve the full column specification
#> i Specify the column types or set `show_col_types = F
```

When you run `read_csv()`, it prints out a message telling you the number of rows and columns of data, the delimiter that was used, and the column specifications (names of columns organized by the type of data the column contains). It also prints out some information about retrieving the full column specification and how to quiet this message. This message is an integral part of `readr`, and we'll return to it in [Section 8.3](#).

8.2.1 Practical advice

Once you read data in, the first step usually involves transforming it in some way to make it easier to work with in the rest of your analysis. Let's take another look at the `students` data with that in mind.

In the `favourite.food` column, there are a bunch of food items, and then the character string `N/A`, which should have been a real `NA` that R will recognize as “not available”. This is something we can address using the `na` argument.

```
students <- read_csv("data/students.csv", na = c("N/A",
students
```

```
#> # A tibble: 6 × 5
#>   `Student ID` `Full Name`     favourite.food    meal
#>   <dbl> <chr>                <chr>             <chr>
#> 1 1 Sunil Huffmann  Strawberry yoghurt  Lunc
#> 2 2 Barclay Lynn   French fries      Lunc
#> 3 3 Jayendra Lyne  <NA>              Breac
#> 4 4 Leon Rossini   Anchovies       Lunc
#> 5 5 Chidiegwu Dunkel Pizza      Pizza            Breac
#> 6 6 Güvenç Attila   Ice cream       Lunc
```

You might also notice that the Student ID and Full Name columns are surrounded by backticks. That's because they contain spaces, breaking R's usual rules for variable names. To refer to them, you need to use those backticks:

```
students |>
  rename(
    student_id = `Student ID`,
    full_name = `Full Name`
  )
#> # A tibble: 6 × 5
#>   student_id full_name     favourite.food    meal
#>   <dbl> <chr>                <chr>             <chr>
#> 1 1 Sunil Huffmann  Strawberry yoghurt  Lunc
#> 2 2 Barclay Lynn   French fries      Lunc
#> 3 3 Jayendra Lyne  <NA>              Breac
#> 4 4 Leon Rossini   Anchovies       Lunc
#> 5 5 Chidiegwu Dunkel Pizza      Pizza            Breac
#> 6 6 Güvenç Attila   Ice cream       Lunc
```

An alternative approach is to use `janitor::clean_names()` to use some heuristics to turn them all into snake case at once¹.

```
students |> janitor::clean_names()
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food    meal
#>       <dbl> <chr>          <chr>           <chr>
#> 1         1 Sunil Huffmann Strawberry yoghurt Lunc
#> 2         2 Barclay Lynn    French fries      Lunc
#> 3         3 Jayendra Lyne  <NA>             Breac
#> 4         4 Leon Rossini   Anchovies       Lunc
#> 5         5 Chidiegwu Dunkel Pizza          Breac
#> 6         6 Güvenç Attila   Ice cream       Lunc
```

Another common task after reading in data is to consider variable types. For example, `meal_type` is a categorical variable with a known set of possible values, which in R should be represented as a factor:

```
students |>
  janitor::clean_names() |>
  mutate(
    meal_plan = factor(meal_plan)
  )
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food    meal
#>       <dbl> <chr>          <chr>           <fct>
#> 1         1 Sunil Huffmann Strawberry yoghurt Lunc
#> 2         2 Barclay Lynn    French fries      Lunc
#> 3         3 Jayendra Lyne  <NA>             Breac
#> 4         4 Leon Rossini   Anchovies       Lunc
#> 5         5 Chidiegwu Dunkel Pizza          Breac
#> 6         6 Güvenç Attila   Ice cream       Lunc
```

Note that the values in the `meal_type` variable have stayed the same, but the type of variable denoted underneath the variable name has changed from character (`<chr>`) to factor (`<fct>`). You'll learn more about factors in [Chapter 18](#).

Before you analyze these data, you'll probably want to fix the `age` column. Currently, it's a character variable because one of the observations is typed out as `five` instead of a numeric `5`. We discuss the details of fixing this issue in [Chapter 22](#).

```
students <- students |>
  janitor::clean_names() |>
  mutate(
    meal_plan = factor(meal_plan),
    age = parse_number(if_else(age == "five", "5", age))
  )

students
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food   meal
#>   <dbl> <chr>           <chr>            <fct>
#> 1 1 Sunil Huffmann  Strawberry yoghurt Lunc
#> 2 2 Barclay Lynn   French fries       Lunc
#> 3 3 Jayendra Lyne  <NA>              Breac
#> 4 4 Leon Rossini   Anchovies        Lunc
#> 5 5 Chidiegwu Dunkel Pizza          Breac
#> 6 6 Güvenç Attila   Ice cream        Lunc
```

8.2.2 Other arguments

There are a couple of other important arguments that we need to mention, and they'll be easier to demonstrate if we first show you a

handy trick: `read_csv()` can read CSV files that you've created in a string:

```
read_csv(  
  "a,b,c  
  1,2,3  
  4,5,6"  
)  
#> # A tibble: 2 × 3  
#>   a     b     c  
#> <dbl> <dbl> <dbl>  
#> 1     1     2     3  
#> 2     4     5     6
```

Usually, `read_csv()` uses the first line of the data for the column names, which is a very common convention. But it's not uncommon for a few lines of metadata to be included at the top of the file. You can use `skip = n` to skip the first `n` lines or use `comment = "#"` to drop all lines that start with (e.g.) `#`:

```
read_csv(  
  "The first line of metadata  
  The second line of metadata  
  x,y,z  
  1,2,3",  
  skip = 2  
)  
#> # A tibble: 1 × 3  
#>   x     y     z  
#> <dbl> <dbl> <dbl>  
#> 1     1     2     3  
  
read_csv(  
  "# A comment I want to skip  
  x,y,z
```

```
 1,2,3",
comment = "#"
)
#> # A tibble: 1 × 3
#>       x     y     z
#>   <dbl> <dbl> <dbl>
#> 1     1     2     3
```

In other cases, the data might not have column names. You can use `col_names = FALSE` to tell `read_csv()` not to treat the first row as headings and instead label them sequentially from X1 to Xn:

```
read_csv(
  "1,2,3
  4,5,6",
  col_names = FALSE
)
#> # A tibble: 2 × 3
#>       X1     X2     X3
#>   <dbl> <dbl> <dbl>
#> 1     1     2     3
#> 2     4     5     6
```

Alternatively, you can pass `col_names` a character vector which will be used as the column names:

```
read_csv(
  "1,2,3
  4,5,6",
  col_names = c("x", "y", "z")
)
#> # A tibble: 2 × 3
#>       x     y     z
#>   <dbl> <dbl> <dbl>
#> 1     1     2     3
#> 2     4     5     6
```

These arguments are all you need to know to read the majority of CSV files that you'll encounter in practice. (For the rest, you'll need to carefully inspect your `.csv` file and read the documentation for `read_csv()`'s many other arguments.)

8.2.3 Other file types

Once you've mastered `read_csv()`, using `readr`'s other functions is straightforward; it's just a matter of knowing which function to reach for:

- `read_csv2()` reads semicolon-separated files. These use `;` instead of `,` to separate fields and are common in countries that use `,` as the decimal marker.
- `read_tsv()` reads tab-delimited files.
- `read_delim()` reads in files with any delimiter, attempting to automatically guess the delimiter if you don't specify it.
- `read_fwf()` reads fixed-width files. You can specify fields by their widths with `fwf_widths()` or by their positions with `fwf_positions()`.
- `read_table()` reads a common variation of fixed-width files where columns are separated by white space.
- `read_log()` reads Apache-style log files.

8.2.4 Exercises

1. What function would you use to read a file where fields were separated with “|”?
2. Apart from `file`, `skip`, and `comment`, what other arguments do `read_csv()` and `read_tsv()` have in common?

3. What are the most important arguments to `read_fwf()`?
4. Sometimes strings in a CSV file contain commas. To prevent them from causing problems, they need to be surrounded by a quoting character, like `"` or `'`. By default, `read_csv()` assumes that the quoting character will be `"`. To read the following text into a data frame, what argument to `read_csv()` do you need to specify?

```
"x,y\n1,'a,b'"
```

5. Identify what is wrong with each of the following inline CSV files. What happens when you run the code?

```
read_csv("a,b\n1,2,3\n4,5,6")
read_csv("a,b,c\n1,2\n1,2,3,4")
read_csv("a,b\n\n\"1\"")
read_csv("a,b\n1,2\nna,b")
read_csv("a;b\n1;3")
```

6. Practice referring to non-syntactic names in the following data frame by:

- Extracting the variable called `1`.
- Plotting a scatterplot of `1` vs. `2`.
- Creating a new column called `3`, which is `2` divided by `1`.
- Renaming the columns to `one`, `two`, and `three`.

```
annoying <- tibble(
  `1` = 1:10,
  `2` = `1` * 2 + rnorm(length(`1`))
)
```

8.3 Controlling column types

A CSV file doesn't contain any information about the type of each variable (i.e., whether it's a logical, number, string, etc.), so `readr` will try to guess the type. This section describes how the guessing process works, how to resolve some common problems that cause it to fail, and, if needed, how to supply the column types yourself. Finally, we'll mention a few general strategies that are useful if `readr` is failing catastrophically and you need to get more insight into the structure of your file.

8.3.1 Guessing types

`readr` uses a heuristic to figure out the column types. For each column, it pulls the values of 1,000² rows spaced evenly from the first row to the last, ignoring missing values. It then works through the following questions:

- Does it contain only `F`, `T`, `FALSE`, or `TRUE` (ignoring case)? If so, it's a logical.
- Does it contain only numbers (e.g., `1`, `-4.5`, `5e6`, `Inf`)? If so, it's a number.
- Does it match the ISO8601 standard? If so, it's a date or date-time. (We'll return to date-times in more detail in [Section 19.2](#)).
- Otherwise, it must be a string.

You can see that behavior in action in this simple example:

```
read_csv("logical,numeric,date,string  
TRUE,1,2021-01-15,abc  
false,4.5,2021-02-15,def  
T,Inf,2021-02-16,ghi")  
#> Rows: 3 Columns: 4  
#> — Column specification —
```

```
#> #> Delimiter: ","
#> #> chr (1): string
#> #> dbl (1): numeric
#> #> lgl (1): logical
#> #> date (1): date
#>
#> #> i Use `spec()` to retrieve the full column specification
#> #> i Specify the column types or set `show_col_types = F
#> #> # A tibble: 3 × 4
#>   logical numeric date      string
#>   <lgsl>     <dbl> <date>    <chr>
#> 1 TRUE        1  2021-01-15 abc
#> 2 FALSE       4.5 2021-02-15 def
#> 3 TRUE        Inf 2021-02-16 ghi
```

This heuristic works well if you have a clean dataset, but in real life, you'll encounter a selection of weird and beautiful failures.

8.3.2 Missing values, column types, and problems

The most common way column detection fails is that a column contains unexpected values, and you get a character column instead of a more specific type. One of the most common causes for this is a missing value, recorded using something other than the NA that stringr expects.

Take this simple 1 column CSV file as an example:

```
csv <- "
x
10
.
20
30"
```

If we read it without any additional arguments, `x` becomes a character column:

```
df <- read_csv(csv)
#> Rows: 4 Columns: 1
#> — Column specification —
#> Delimiter: ","
#> chr (1): x
#>
#> i Use `spec()` to retrieve the full column specification
#> i Specify the column types or set `show_col_types = F
```

In this very small case, you can easily see the missing value `.`. But what happens if you have thousands of rows with only a few missing values represented by `.`s speckled among them? One approach is to tell `readr` that `x` is a numeric column, and then see where it fails. You can do that with the `col_types` argument, which takes a named list:

```
df <- read_csv(csv, col_types = list(x = col_double()))
#> Warning: One or more parsing issues, call `problems()
#> details, e.g.:
#>   dat <- vroom(. . .)
#>   problems(dat)
```

Now `read_csv()` reports that there was a problem, and tells us we can find out more with `problems()`:

```
problems(df)
#> # A tibble: 1 × 5
#>   row     col expected actual file
```

```
#> <int> <int> <chr>     <chr>   <chr>
#> 1      3       1 a double .      /tmp/RtmpFqB2Eg/file1e8
```

This tells us that there was a problem in row 3, col 1 where `readr` expected a double but got a `.`. That suggests this dataset uses `.` for missing values. So then we set `na = ".."`, the automatic guessing succeeds, giving us the numeric column that we want:

```
df <- read_csv(csv, na = ".")
#> Rows: 4 Columns: 1
#> — Column specification —
#> Delimiter: ","
#> dbl (1): x
#>
#> i Use `spec()` to retrieve the full column specification
#> i Specify the column types or set `show_col_types = F
```

8.3.3 Column types

`readr` provides a total of nine column types for you to use:

- `col_logical()` and `col_double()` read logicals and real numbers. They're relatively rarely needed (except as above), since `readr` will usually guess them for you.
- `col_integer()` reads integers. We distinguish integers and doubles in this book because they're functionally equivalent, but reading integers explicitly can occasionally be useful because they occupy half the memory of doubles.
- `col_character()` reads strings. This is sometimes useful to specify explicitly when you have a column that is a numeric identifier, i.e. long series of digits that identifies some object, but it doesn't make sense to (e.g.) divide it in half.

- `col_factor()`, `col_date()`, and `col_datetime()` create factors, dates, and date-times respectively; you'll learn more about those when we get to those data types in [Chapter 18](#) and [Chapter 19](#).
- `col_number()` is a permissive numeric parser that will ignore non-numeric components, and is particularly useful for currencies. You'll learn more about it in [Chapter 15](#).
- `col_skip()` skips a column so it's not included in the result.

It's also possible to override the default column by switching from `list()` to `cols()`:

```
csv <- "  
x,y,z  
1,2,3"  
  
read_csv(csv, col_types = cols-.default = col_character()  
#> # A tibble: 1 × 3  
#>   x     y     z  
#>   <chr> <chr> <chr>  
#> 1 1     2     3
```

Another useful helper is `cols_only()` which will read in only the columns you specify:

```
read_csv(  
  "x,y,z  
  1,2,3",  
  col_types = cols_only(x = col_character())  
)  
#> # A tibble: 1 × 1  
#>   x
```

```
#> <chr>
#> 1 1
```

8.4 Reading data from multiple files

Sometimes your data is split across multiple files instead of being contained in a single file. For example, you might have sales data for multiple months, with each month's data in a separate file: `01-sales.csv` for January, `02-sales.csv` for February, and `03-sales.csv` for March. With `read_csv()` you can read these data in at once and stack them on top of each other in a single data frame.

```
sales_files <- c("data/01-sales.csv", "data/02-sales.csv",
read_csv(sales_files, id = "file")
#> Rows: 19 Columns: 6
#> — Column specification —
#> Delimiter: ","
#> chr (1): month
#> dbl (4): year, brand, item, n
#>
#> i Use `spec()` to retrieve the full column specification
#> i Specify the column types or set `show_col_types = F
#> # A tibble: 19 × 6
#>   file          month    year  brand  item     n
#>   <chr>        <chr>  <dbl> <dbl> <dbl> <dbl>
#> 1 data/01-sales.csv January 2019     1 1234     3
#> 2 data/01-sales.csv January 2019     1 8721     9
#> 3 data/01-sales.csv January 2019     1 1822     2
#> 4 data/01-sales.csv January 2019     2 3333     1
#> 5 data/01-sales.csv January 2019     2 2156     9
#> 6 data/01-sales.csv January 2019     2 3987     6
#> # ... with 13 more rows
```

With the additional `id` parameter we have added a new column called `file` to the resulting data frame that identifies the file the data come from. This is especially helpful in circumstances where the files you're reading in do not have an identifying column that can help you trace the observations back to their original sources.

If you have many files you want to read in, it can get cumbersome to write out their names as a list. Instead, you can use the base `list.files()` function to find the files for you by matching a pattern in the file names. You'll learn more about these patterns in [Chapter 17](#).

```
sales_files <- list.files("data", pattern = "sales\\*.csv"
sales_files
#> [1] "data/01-sales.csv" "data/02-sales.csv" "data/03-
```

8.5 Writing to a file

`readr` also comes with two useful functions for writing data back to disk: `write_csv()` and `write_tsv()`. Both functions increase the chances of the output file being read back in correctly by using the standard UTF-8 encoding for strings and ISO8601 format for date-times.

The most important arguments are `x` (the data frame to save), and `file` (the location to save it). You can also specify how missing values are written with `na`, and if you want to `append` to an existing file.

```
write_csv(students, "students.csv")
```

Now let's read that csv file back in. Note that the type information is lost when you save to csv:

```
students
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food     meal
#>       <dbl> <chr>          <chr>           <fct>
#> 1         1 Sunil Huffmann Strawberry yoghurt Lunc
#> 2         2 Barclay Lynn    French fries      Lunc
#> 3         3 Jayendra Lyne  <NA>             Breac
#> 4         4 Leon Rossini   Anchovies       Lunc
#> 5         5 Chidiegwu Dunkel Pizza           Breac
#> 6         6 Güvenç Attila   Ice cream       Lunc
write_csv(students, "students-2.csv")
read_csv("students-2.csv")
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food     meal
#>       <dbl> <chr>          <chr>           <chr>
#> 1         1 Sunil Huffmann Strawberry yoghurt Lunc
#> 2         2 Barclay Lynn    French fries      Lunc
#> 3         3 Jayendra Lyne  <NA>             Breac
#> 4         4 Leon Rossini   Anchovies       Lunc
#> 5         5 Chidiegwu Dunkel Pizza           Breac
#> 6         6 Güvenç Attila   Ice cream       Lunc
```

This makes CSVs a little unreliable for caching interim results—you need to recreate the column specification every time you load in. There are two main alternative:

1. `write_rds()` and `read_rds()` are uniform wrappers around the base functions `readRDS()` and `saveRDS()`. These store data in R's custom binary format called RDS:

```
write_rds(students, "students.rds")
read_rds("students.rds")
#> # A tibble: 6 × 5
```

```
#>   student_id full_name      favourite_food
#>   <dbl> <chr>           <chr>
#> 1     1 Sunil Huffmann  Strawberry yoghurt
#> 2     2 Barclay Lynn    French fries
#> 3     3 Jayendra Lyne   <NA>
#> 4     4 Leon Rossini   Anchovies
#> 5     5 Chidiegwu Dunkel Pizza
#> 6     6 Güvenç Attila   Ice cream
```

2. The arrow package allows you to read and write parquet files, a fast binary file format that can be shared across programming languages. We'll return to arrow in more depth in [Chapter 24](#).

```
library(arrow)
write_parquet(students, "students.parquet")
read_parquet("students.parquet")
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food
#>   <dbl> <chr>           <chr>
#> 1     1 Sunil Huffmann  Strawberry yoghurt
#> 2     2 Barclay Lynn    French fries
#> 3     3 Jayendra Lyne   NA
#> 4     4 Leon Rossini   Anchovies
#> 5     5 Chidiegwu Dunkel Pizza
#> 6     6 Güvenç Attila   Ice cream
```

Parquet tends to be much faster than RDS and is usable outside of R, but does require the arrow package.

8.6 Data entry

Sometimes you'll need to assemble a tibble "by hand" doing a little data entry in your R script. There are two useful functions to help you do this which differ in whether you layout the tibble by columns or by rows.

`tibble()` works by column:

```
tibble(  
  x = c(1, 2, 5),  
  y = c("h", "m", "g"),  
  z = c(0.08, 0.83, 0.60)  
)  
#> # A tibble: 3 × 3  
#>   x     y     z  
#>   <dbl> <chr> <dbl>  
#> 1     1 h     0.08  
#> 2     2 m     0.83  
#> 3     5 g     0.6
```

Note that every column in tibble must be same size, so you'll get an error if they're not:

```
tibble(  
  x = c(1, 2),  
  y = c("h", "m", "g"),  
  z = c(0.08, 0.83, 0.6)  
)  
#> Error:  
#> ! Tibble columns must have compatible sizes.  
#> • Size 2: Existing data.  
#> • Size 3: Column `y`.  
#> i Only values of size one are recycled.
```

Laying out the data by column can make it hard to see how the rows are related, so an alternative is `tribble()`, short for `transposed tibble`, which lets you lay out your data row by row. `tribble()` is customized for data entry in code: column headings start with `~` and entries are

separated by commas. This makes it possible to lay out small amounts of data in an easy to read form:

```
tribble(  
  ~x, ~y, ~z,  
  "h", 1, 0.08,  
  "m", 2, 0.83,  
  "g", 5, 0.60,  
)  
#> # A tibble: 3 × 3  
#>   x     y     z  
#>   <chr> <dbl> <dbl>  
#> 1 h     1    0.08  
#> 2 m     2    0.83  
#> 3 g     5    0.6
```

We'll use `tibble()` and `tribble()` later in the book to construct small examples to demonstrate how various functions work.

8.7 Summary

In this chapter, you've learned how to load CSV files with `read_csv()` and to do your own data entry with `tibble()` and `tribble()`. You've learned how csv files work, some of the problems you might encounter, and how to overcome them. We'll come to data import a few times in this book: [Chapter 22](#) from Excel and googlesheets, [Chapter 23](#) will show you how to load data from databases, [Chapter 24](#) from parquet files, [Chapter 25](#) from JSON, and [Chapter 26](#) from websites.

Now that you're writing a substantial amount of R code, it's time to learn more about organizing your code into files and directories. In the next chapter, you'll learn all about the advantages of scripts and projects, and some of the many tools that they provide to make your life easier.

1. The [janitor](#) package is not part of the tidyverse, but it offers handy functions for data cleaning and works well within data pipelines that uses `|>.`
2. You can override the default of 1000 with the `guess_max` argument.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

This chapter will introduce you to two essential tools for organizing your code: scripts and projects.

9.1 Scripts

So far, you have used the console to run code. That's a great place to start, but you'll find it gets cramped pretty quickly as you create more complex ggplot2 graphics and longer dplyr pipelines. To give yourself more room to work, use the script editor. Open it up by clicking the File menu, selecting New File, then R script, or using the keyboard shortcut Cmd/Ctrl + Shift + N. Now you'll see four panes, as in [Figure 9.1](#). The script editor is a great place to put code you care about. Keep experimenting in the console, but once you have written code that works and does what you want, put it in the script editor.

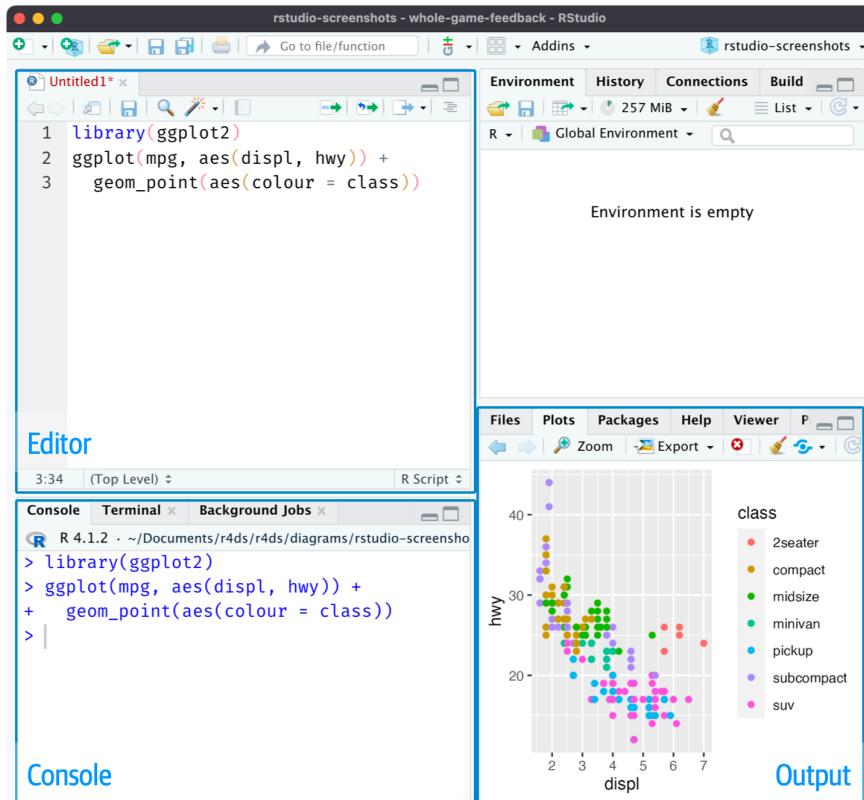

Figure 9.1: Opening the script editor adds a new pane at the top-left of the IDE.

9.1.1 Running code

The script editor is an excellent place for building complex ggplot2 plots or long sequences of dplyr manipulations. The key to using the script editor effectively is to memorize one of the most important keyboard shortcuts: Cmd/Ctrl + Enter. This executes the current R expression in the console. For example, take the code below. If your cursor is at , pressing Cmd/Ctrl + Enter will run the complete command that generates `not_cancelled`. It will also move the cursor to the following statement (beginning with `not_cancelled >`). That makes it easy to

step through your complete script by repeatedly pressing Cmd/Ctrl + Enter.

```
library(dplyr)
library(nycflights13)

not_cancelled <- flights |>
  filter(!is.na(dep_delay), !is.na(arr_delay))

not_cancelled |>
  group_by(year, month, day) |>
  summarize(mean = mean(dep_delay))
```

Instead of running your code expression-by-expression, you can also execute the complete script in one step with Cmd/Ctrl + Shift + S. Doing this regularly is a great way to ensure that you've captured all the important parts of your code in the script.

We recommend you always start your script with the packages you need. That way, if you share your code with others, they can easily see which packages they need to install. Note, however, that you should never include `install.packages()` in a script you share. It's very antisocial to change settings on someone else's computer!

When working through future chapters, we highly recommend starting in the script editor and practicing your keyboard shortcuts. Over time, sending code to the console in this way will become so natural that you won't even think about it.

9.1.2 RStudio diagnostics

In the script editor, RStudio will highlight syntax errors with a red squiggly line and a cross in the sidebar:

Script editor with the script `x y <- 10`. A red X indicates that there is a syntax error. The syntax error is also highlighted with a red squiggly line.

Hover over the cross to see what the problem is:

Script editor with the script `x y <- 10`. A red X indicates that there is a syntax error. The syntax error is also highlighted with a red squiggly line. Hovering over the X shows a text box with the text unexpected token y and unexpected token <-.

RStudio will also let you know about potential problems:

Script editor with the script `3 == NA`. A yellow exclamation mark indicates that there may be a potential problem. Hovering over the exclamation mark shows a text box with the text use `is.na` to check whether expression evaluates to NA.

9.1.3 Saving and naming

RStudio automatically saves the contents of the script editor when you quit, and automatically reloads it when you re-open. Nevertheless, it's a good idea to avoid Untitled1, Untitled2, Untitled3, and so on and instead save your scripts and to give them informative names.

It might be tempting to name your files `code.R` or `myscript.R`, but you should think a bit harder before choosing a name for your file. Three important principles for file naming are as follows:

1. File names should be **machine** readable: avoid spaces, symbols, and special characters. Don't rely on case sensitivity to distinguish files.
2. File names should be **human** readable: use file names to describe what's in the file.

3. File names should play well with default ordering: start file names with numbers so that alphabetical sorting puts them in the order they get used.

For example, suppose you have the following files in a project folder.

```
alternative model.R  
code for exploratory analysis.r  
finalreport.qmd  
FinalReport.qmd  
fig 1.png  
Figure_02.png  
model_first_try.R  
run-first.r  
temp.txt
```

There are a variety of problems here: it's hard to find which file to run first, file names contain spaces, there are two files with the same name but different capitalization (`finalreport` vs. `FinalReport`¹), and some names don't describe their contents (`run-first` and `temp`).

Here's better way of naming and organizing the same set of files:

```
01-load-data.R  
02-exploratory-analysis.R  
03-model-approach-1.R  
04-model-approach-2.R  
fig-01.png  
fig-02.png  
report-2022-03-20.qmd  
report-2022-04-02.qmd  
report-draft-notes.txt
```

Numbering the key scripts make it obvious in which order to run them and a consistent naming scheme makes it easier to see what varies. Additionally, the figures are labelled similarly, the reports are

distinguished by dates included in the file names, and `temp` is renamed to `report-draft-notes` to better describe its contents.

9.2 Projects

One day, you will need to quit R, go do something else, and return to your analysis later. One day, you will be working on multiple analyses simultaneously and you want to keep them separate. One day, you will need to bring data from the outside world into R and send numerical results and figures from R back out into the world.

To handle these real life situations, you need to make two decisions:

1. What is the source of truth? What will you save as your lasting record of what happened?
2. Where does your analysis live?

9.2.1 What is the source of truth?

As a beginning R user, it's OK to consider your environment (i.e. the objects listed in the environment pane) to be your analysis. However, in the long run, you'll be much better off if you ensure that your R scripts are the source of truth. With your R scripts (and your data files), you can recreate the environment. With only your environment, it's much harder to recreate your R scripts: you'll either have to retype a lot of code from memory (inevitably making mistakes along the way) or you'll have to carefully mine your R history.

To help keep your R scripts as the source of truth for your analysis, we highly recommend that you instruct RStudio not to preserve your workspace between sessions. You can do this either by running `usethis::use_blank_slate()`² or by mimicking the options shown

in [Figure 9.2](#). This will cause you some short-term pain, because now when you restart RStudio, it will no longer remember the code that you ran last time. But this short-term pain saves you long-term agony because it forces you to capture all important interactions in your code. There's nothing worse than discovering three months after the fact that you've only stored the results of an important calculation in your workspace, not the calculation itself in your code.

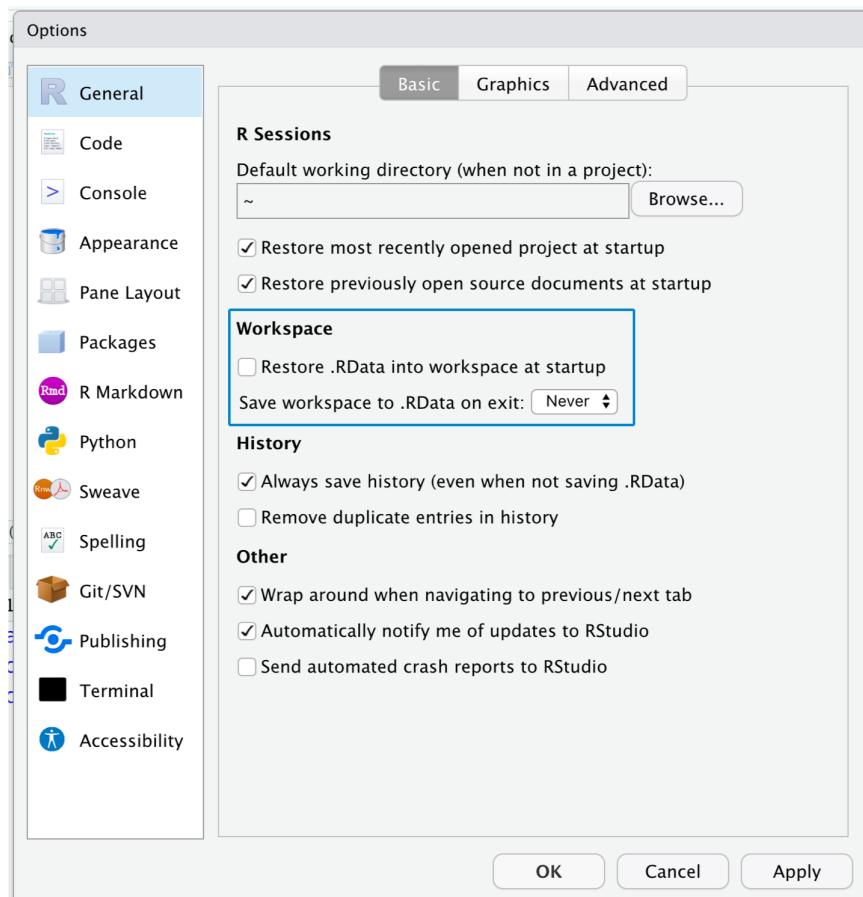

Figure 9.2: Copy these options in your RStudio options to always start your RStudio session with a clean slate.

There is a great pair of keyboard shortcuts that will work together to make sure you've captured the important parts of your code in the editor:

1. Press Cmd/Ctrl + Shift + F10 to restart R.
2. Press Cmd/Ctrl + Shift + S to re-run the current script.

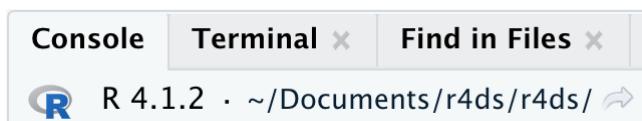

We collectively use this pattern hundreds of times a week.

RStudio server

If you're using RStudio server, your R session is never restarted by default. When you close your RStudio server tab, it might feel like you're closing R, but the server actually keeps it running in the background. The next time you return, you'll be in exactly the same place you left. This makes it even more important to regularly restart R so that you're starting with a refresh slate.

9.2.2 Where does your analysis live?

R has a powerful notion of the **working directory**. This is where R looks for files that you ask it to load, and where it will put any files that you ask it to save. RStudio shows your current working directory at the top of the console:

And you can print this out in R code by running `getwd()`:

```
getwd()  
#> [1] "/Users/hadley/Documents/r4ds/r4ds"
```

As a beginning R user, it's OK to let your working directory be your home directory, documents directory, or any other weird directory on your computer. But you're nine chapters into this book, and you're no longer a rank beginner. Very soon now you should evolve to organizing your projects into directories and, when working on a project, set R's working directory to the associated directory.

You can set the working directory from within R but **we do not recommend it:**

```
setwd("/path/to/my/CoolProject")
```

There's a better way; a way that also puts you on the path to managing your R work like an expert. That way is the **RStudio project**.

9.2.3 RStudio projects

Keeping all the files associated with a given project (input data, R scripts, analytical results, and figures) together in one directory is such a wise and common practice that RStudio has built-in support for this via **projects**. Let's make a project for you to use while you're working through the rest of this book. Click File > New Project, then follow the steps shown in [Figure 9.3](#).

New Project Wizard

Create Project

-  **New Directory**
Start a project in a brand new working directory >
-  **Existing Directory**
Associate a project with an existing working directory >
-  **Version Control**
Checkout a project from a version control repository >

Cancel

(a) First click New Directory.

New Project Wizard

Project Type

Back

-  **New Project** >
-  **R Package** >
-  **Shiny Application** >
-  **Quarto Project** >
-  **Quarto Website** >
-  **Quarto Blog** >
-  **Quarto Book** >

Cancel

(b) Then click New Project.

Call your project `r4ds` and think carefully about which subdirectory

New Project Wizard

Back Create New Project

Directory name:
`r4ds`

Create project as subdirectory of:

```
getwd()  
#> [1] /Users/hadley/Documents/r4ds/r4ds
```

Open in new session Create Project Cancel

```
library(tidyverse)  
  
ggplot(diamonds, aes(x = carat, y = price)) +  
  geom_hex()  
ggsave("diamonds.pdf")  
  
write_csv(diamonds, "diamonds.csv")
```

Quit RStudio. Inspect the folder associated with your project — notice the `.Rproj` file. Double-click that file to re-open the project. Notice you get back to where you left off: it's the same working directory and command history, and all the files you were working on are still open. Because you followed our instructions above, you will, however, have a completely fresh environment, guaranteeing that you're starting with a clean slate.

In your favorite OS-specific way, search your computer for `diamonds.pdf` and you will find the PDF (no surprise) but *also the*

script that created it (`diamonds.R`). This is a huge win! One day, you will want to remake a figure or just understand where it came from. If you rigorously save figures to files **with R code** and never with the mouse or the clipboard, you will be able to reproduce old work with ease!

9.2.4 Relative and absolute paths

Once you’re inside a project, you should only ever use relative paths not absolute paths. What’s the difference? A relative path is **relative** to the working directory, i.e. the project’s home. When Hadley wrote `diamonds.R` above it was a shortcut for

`/Users/hadley/Documents/r4ds/r4ds/diamonds.R`. But importantly, if Mine ran this code on her computer, it would point to `/Users/Mine/Documents/r4ds/r4ds/diamonds.R`. This is why relative paths are important: they’ll work regardless of where the project ends up.

Absolute paths point to the same place regardless of your working directory. They look a little different depending on your operating system. On Windows they start with a drive letter (e.g. `C:`) or two backslashes (e.g. `\servername`) and on Mac/Linux they start with a slash “`/`” (e.g. `/users/hadley`). You should **never** use absolute paths in your scripts, because they hinder sharing: no one else will have exactly the same directory configuration as you.

There’s another important difference between operating systems: how you separate the components of the path. Mac and Linux uses slashes (e.g. `plots/diamonds.pdf`) and Windows uses backslashes (e.g. `plots\diamonds.pdf`). R can work with either type (no matter what platform you’re currently using), but unfortunately, backslashes mean something special to R, and to get a single backslash in the path,

you need to type two backslashes! That makes life frustrating, so we recommend always using the Linux/Mac style with forward slashes.

9.3 Summary

In summary, scripts and projects give you a solid workflow that will serve you well in the future:

- Create one RStudio project for each data analysis project.
- Save your scripts (with informative names) in the project, edit them, run them in bits or as a whole. Restart R frequently to make sure you've captured everything in your scripts.
- Only ever use relative paths, not absolute paths.

Then everything you need is in one place and cleanly separated from all the other projects that you are working on.

9.4 Exercises

1. Go to the RStudio Tips Twitter account, <https://twitter.com/rstudiotips> and find one tip that looks interesting. Practice using it!
2. What other common mistakes will RStudio diagnostics report? Read <https://support.posit.co/hc/en-us/articles/205753617-Code-Diagnostics> to find out.

9.5 Summary

In this chapter, you've learned how to organize your R code in scripts (files) and projects (directories). Much like code style, this may feel like

busywork at first. But as you accumulate more code across multiple projects, you'll learn to appreciate how a little up front organisation can save you a bunch of time down the road.

Next up, you'll learn about how to get help and how to ask good coding questions.

1. Not to mention that you're tempting fate by using "final" in the name 😅 The comic piled higher and deeper has a [fun strip on this](#). 
2. If you don't have usethis installed, you can install it with
`install.packages("usethis")` 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

This book is not an island; there is no single resource that will allow you to master R. As you begin to apply the techniques described in this book to your own data, you will soon find questions that we do not answer. This section describes a few tips on how to get help and to help you keep learning.

10.1 Google is your friend

If you get stuck, start with Google. Typically adding “R” to a query is enough to restrict it to relevant results: if the search isn’t useful, it often means that there aren’t any R-specific results available. Google is particularly useful for error messages. If you get an error message and you have no idea what it means, try googling it! Chances are that someone else has been confused by it in the past, and there will be help somewhere on the web. (If the error message isn’t in English, run `Sys.setenv(LANGUAGE = "en")` and re-run the code; you’re more likely to find help for English error messages.)

If Google doesn’t help, try [Stack Overflow](#). Start by spending a little time searching for an existing answer, including [R], to restrict your search to questions and answers that use R.

10.2 Making a reprex

If your googling doesn't find anything useful, it's a really good idea to prepare a **reprex**, short for minimal **reproducible example**. A good reprex makes it easier for other people to help you, and often you'll figure out the problem yourself in the course of making it. There are two parts to creating a reprex:

- First, you need to make your code reproducible. This means that you need to capture everything, i.e., include any `library()` calls and create all necessary objects. The easiest way to make sure you've done this is using the `reprex` package.
- Second, you need to make it minimal. Strip away everything that is not directly related to your problem. This usually involves creating a much smaller and simpler R object than the one you're facing in real life or even using built-in data.

That sounds like a lot of work! And it can be, but it has a great payoff:

- 80% of the time, creating an excellent reprex reveals the source of your problem. It's amazing how often the process of writing up a self-contained and minimal example allows you to answer your own question.
- The other 20% of the time, you will have captured the essence of your problem in a way that is easy for others to play with. This substantially improves your chances of getting help!

When creating a reprex by hand, it's easy to accidentally miss something, meaning your code can't be run on someone else's computer. Avoid this problem by using the `reprex` package, which is

installed as part of the tidyverse. Let's say you copy this code onto your clipboard (or, on RStudio Server or Cloud, select it):

```
y <- 1:4  
mean(y)
```

Then call `reprex()`, where the default target venue is GitHub:

```
reprex::reprex()
```

A nicely rendered HTML preview will display in RStudio's Viewer (if you're in RStudio) or your default browser otherwise. The relevant bit of GitHub-flavored Markdown is ready to be pasted from your clipboard (on RStudio Server or Cloud, you will need to copy this yourself):

```
``` r  
y <- 1:4
mean(y)
#> [1] 2.5
```
```

Here's what that Markdown would look like rendered in a GitHub issue:

```
y <- 1:4  
mean(y)  
#> [1] 2.5
```

Anyone else can copy, paste, and run this immediately.

There are three things you need to include to make your example reproducible: required packages, data, and code.

1. **Packages** should be loaded at the top of the script so it's easy to see which ones the example needs. This is a good time to check that you're using the latest version of each package; you may have

discovered a bug that's been fixed since you installed or last updated the package. For packages in the tidyverse, the easiest way to check is to run `tidyverse_update()`.

2. The easiest way to include **data** is to use `dput()` to generate the R code needed to recreate it. For example, to recreate the `mtcars` dataset in R, perform the following steps:

1. Run `dput(mtcars)` in R
2. Copy the output
3. In reprex, type `mtcars <-`, then paste.

Try and find the smallest subset of your data that still reveals the problem.

3. Spend a little bit of time ensuring that your **code** is easy for others to read:

- o Make sure you've used spaces and your variable names are concise yet informative.
- o Use comments to indicate where your problem lies.
- o Do your best to remove everything that is not related to the problem.

The shorter your code is, the easier it is to understand and the easier it is to fix.

Finish by checking that you have actually made a reproducible example by starting a fresh R session and copying and pasting your script.

10.3 Investing in yourself

You should also spend some time preparing yourself to solve problems before they occur. Investing a little time in learning R each day will pay off handsomely in the long run. One way is to follow what the tidyverse team is doing on the [tidyverse blog](#). To keep up with the R community more broadly, we recommend reading [R Weekly](#): it's a community effort to aggregate the most interesting news in the R community each week.

If you're an active Twitter user, you might also want to follow Hadley ([@hadleywickham](#)), Mine ([@minebocek](#)), Garrett ([@statgarrett](#)), or follow [@rstudiotips](#) to keep up with new features in the IDE. If you want the full fire hose of new developments, you can also read the ([#rstats](#)) hashtag. This is one of the key tools that Hadley and Mine use to keep up with new developments in the community.

10.4 Summary

This chapter concludes the Whole Game part of the book. You've now seen the most important parts of the data science process: visualization, transformation, tidying and importing. Now you've got a holistic view of the whole process, and we start to get into the details of small pieces.

The next part of the book, Visualize, does a deeper dive into the grammar of graphics and creating data visualizations with ggplot2, showcases how to use the tools you've learned so far to conduct exploratory data analysis, and introduces good practices for creating plots for communication.

Visualize

i You are reading the work-in-progress second edition of R for Data Science. This chapter is largely complete and just needs final proof reading. You can find the complete first edition at <https://r4ds.had.co.nz>.

After reading the first two parts of the book, you understand (at least superficially) the most important tools for doing data science. Now it's time to start diving into the details. In this part of the book, you'll learn about visualizing data in further depth.

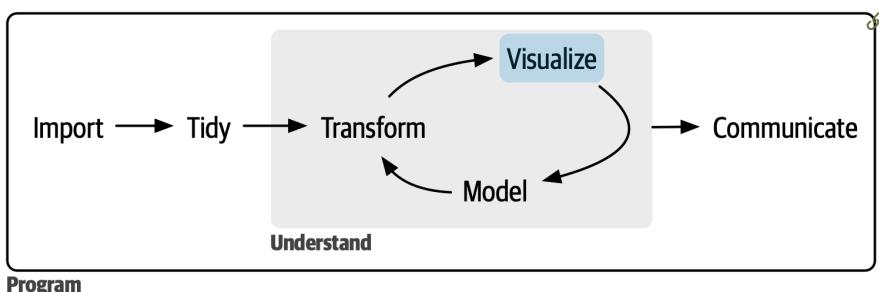

Figure 1: Data visualization is often the first step in data exploration.

Each chapter addresses one to a few aspects of creating a data visualization.

- In [Chapter 11](#) you will learn about the layered grammar of graphics.
- In [Chapter 12](#), you'll combine visualization with your curiosity and skepticism to ask and answer interesting questions about data.
- Finally, in [Chapter 13](#) you will learn how to take your exploratory graphics and turn them into expository graphics, graphics that help

the newcomer to your analysis understand what's going on as quickly and easily as possible.

Learning more

The absolute best place to learn more is the ggplot2 book: *ggplot2: Elegant graphics for data analysis*. It goes into much more depth about the underlying theory, and has many more examples of how to combine the individual pieces to solve practical problems.

Another great resource is the ggplot2 extensions gallery <https://exts.ggplot2.tidyverse.org/gallery/>. This site lists many of the packages that extend ggplot2 with new geoms and scales. It's a great place to start if you're trying to do something that seems hard with ggplot2.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter is largely complete and just needs final proof reading. You can find the complete first edition at <https://r4ds.had.co.nz>.

11.1 Introduction

In the [Chapter 2](#), you learned much more than just how to make scatterplots, bar charts, and boxplots. You learned a foundation that you can use to make *any* type of plot with ggplot2.

In this chapter, you'll expand on that foundation as you learn about the layered grammar of graphics. We'll start with a deeper dive into aesthetic mappings, geometric objects, and facets. Then, you will learn about statistical transformations ggplot2 makes under the hood when creating a plot. These transformations are used to calculate new values to plot, such as the heights of bars in a bar plot or medians in a box plot. You will also learn about position adjustments, which modify how geoms are displayed in your plots. Finally, we'll briefly introduce coordinate systems.

We will not cover every single function and option for each of these layers, but we will walk you through the most important and commonly used functionality provided by ggplot2 as well as introduce you to packages that extend ggplot2.

11.1.1 Prerequisites

This chapter focuses on `ggplot2`, one of the core packages in the `tidyverse`. To access the datasets, help pages, and functions used in this chapter, load the `tidyverse` by running this code:

```
library(tidyverse)
#> — Attaching packages —
#> ✓ ggplot2 3.4.0      ✓ purrr   1.0.1.9000
#> ✓ tibble  3.1.8      ✓ dplyr   1.0.99.9000
#> ✓ tidyr   1.2.1.9001  ✓ stringr 1.5.0
#> ✓ readr   2.1.3      ✓ forcats 0.5.2
#> — Conflicts —
#> ✘ dplyr::filter() masks stats::filter()
#> ✘ dplyr::lag()   masks stats::lag()
```

11.2 Aesthetic mappings

“The greatest value of a picture is when it forces us to notice what we never expected to see.” — John Tukey

The `mpg` data frame that is bundled with the `ggplot2` package contains 234 observations collected by the US Environmental Protection Agency on 38 car models.

```
mpg
#> # A tibble: 234 × 11
#>   manufacturer model displ year cyl trans drv
#>   <chr>        <chr>  <dbl> <int> <int> <chr>  <chr>
#> 1 audi         a4     1.8  1999     4 auto(l5) f
#> 2 audi         a4     1.8  1999     4 manual(... f
#> 3 audi         a4     2    2008     4 manual(... f
#> 4 audi         a4     2    2008     4 auto(av) f
```

```
#> 5 audi          a4        2.8  1999       6 auto(l5) f  
#> 6 audi          a4        2.8  1999       6 manual(... f  
#> # ... with 228 more rows
```

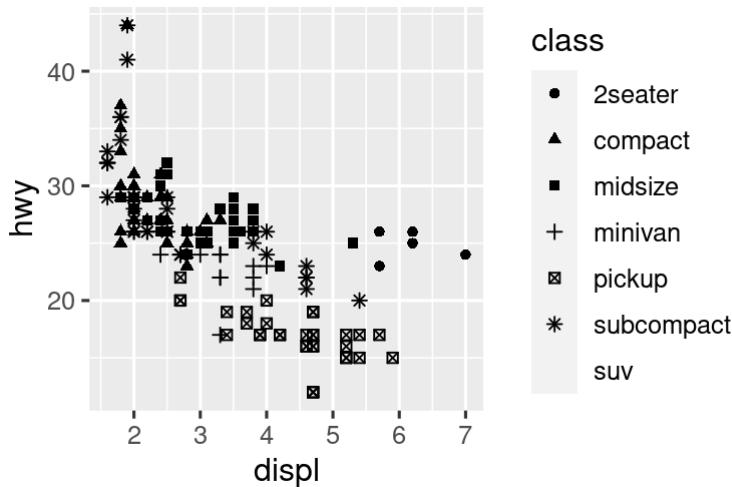

Among the variables in `mpg` are:

1. `displ`: A car's engine size, in liters. A numerical variable.
2. `hwy`: A car's fuel efficiency on the highway, in miles per gallon (mpg). A car with a low fuel efficiency consumes more fuel than a car with a high fuel efficiency when they travel the same distance. A numerical variable.
3. `class`: Type of car. A categorical variable.

You can learn about `mpg` on its help page by running `?mpg`.

Let's start by visualizing the relationship between `displ` and `hwy` for various `class`es of cars. We can do this with a scatterplot where the numerical variables are mapped to the `x` and `y` aesthetics and the categorical variable is mapped to an aesthetic like `color` or `shape`.

```
# Left  
ggplot(mpg, aes(x = displ, y = hwy, color = class)) +  
  geom_point()  
  
# Right  
ggplot(mpg, aes(x = displ, y = hwy, shape = class)) +  
  geom_point()  
#> Warning: The shape palette can deal with a maximum of  
#> because more than 6 becomes difficult to discriminate  
#> Consider specifying shapes manually if you must have  
#> Warning: Removed 62 rows containing missing values (
```

When `class` is mapped to `shape`, we get two warnings:

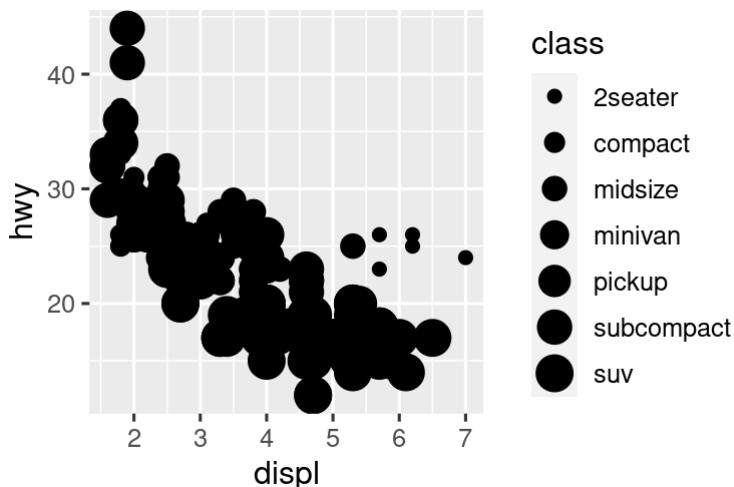

- 1: The shape palette can deal with a maximum of 6 discrete values because more than 6 becomes difficult to discriminate; you have 7. Consider specifying shapes manually if you must have them.
- 2: Removed 62 rows containing missing values (`geom_point()`).

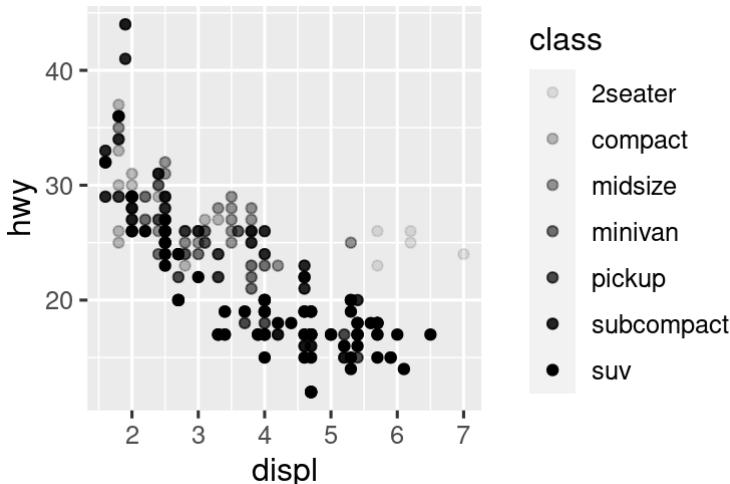

Since ggplot2 will only use six shapes at a time, by default, additional groups will go unplotted when you use the shape aesthetic. The second warning is related – there are 62 SUVs in the dataset and they’re not plotted.

Similarly, we can map `class` to `size` or `alpha` (transparency) aesthetics as well.

```
# Left
ggplot(mpg, aes(x = displ, y = hwy, size = class)) +
  geom_point()
#> Warning: Using size for a discrete variable is not ac

# Right
ggplot(mpg, aes(x = displ, y = hwy, alpha = class)) +
  geom_point()
#> Warning: Using alpha for a discrete variable is not a
```

Both of these produce warnings as well:

Using alpha for a discrete variable is not advised.

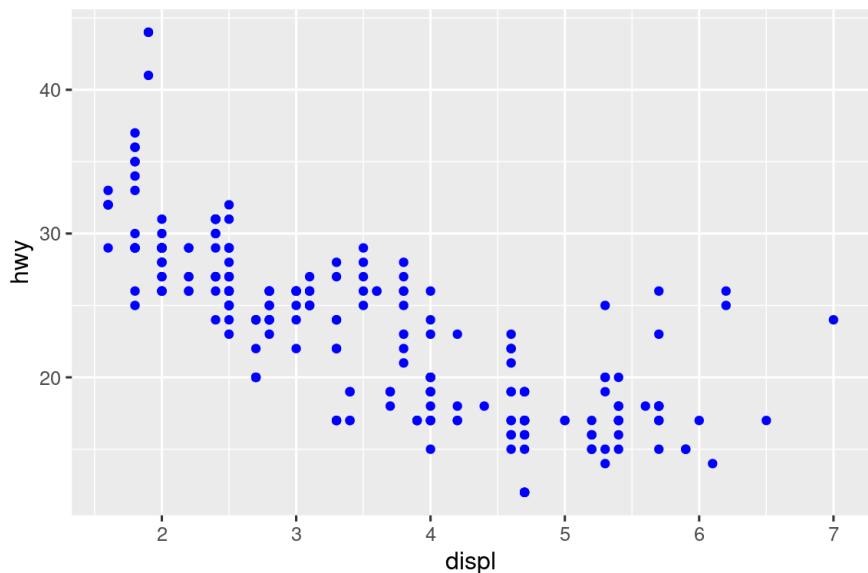

Mapping a non-ordinal discrete (categorical) variable (`class`) to an ordered aesthetic (`size` or `alpha`) is generally not a good idea because it implies a ranking that does not in fact exist.

Similarly, we could have mapped `class` to the `alpha` aesthetic, which controls the transparency of the points, or to the `shape` aesthetic, which controls the shape of the points.

Once you map an aesthetic, ggplot2 takes care of the rest. It selects a reasonable scale to use with the aesthetic, and it constructs a legend that explains the mapping between levels and values. For x and y aesthetics, ggplot2 does not create a legend, but it creates an axis line with tick marks and a label. The axis line acts as a legend; it explains the mapping between locations and values.

You can also set the aesthetic properties of your geom manually. For example, we can make all of the points in our plot blue:

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(color = "blue")
```

Here, the color doesn't convey information about a variable, but only changes the appearance of the plot. You can set an aesthetic manually by name as an argument of your geom function. In other words, it goes *outside of* `aes()`. You'll need to pick a value that makes sense for that aesthetic:

- The name of a color as a character string.
- The size of a point in mm.
- The shape of a point as a number, as shown in [Figure 11.1](#).

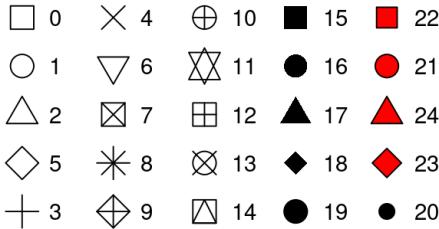

Figure 11.1: R has 25 built in shapes that are identified by numbers.

There are some seeming duplicates: for example, 0, 15, and 22 are all squares. The difference comes from the interaction of the `color` and `fill` aesthetics. The hollow shapes (0–14) have a border determined by `color`; the solid shapes (15–20) are filled with `color`; the filled shapes (21–24) have a border of `color` and are filled with `fill`.

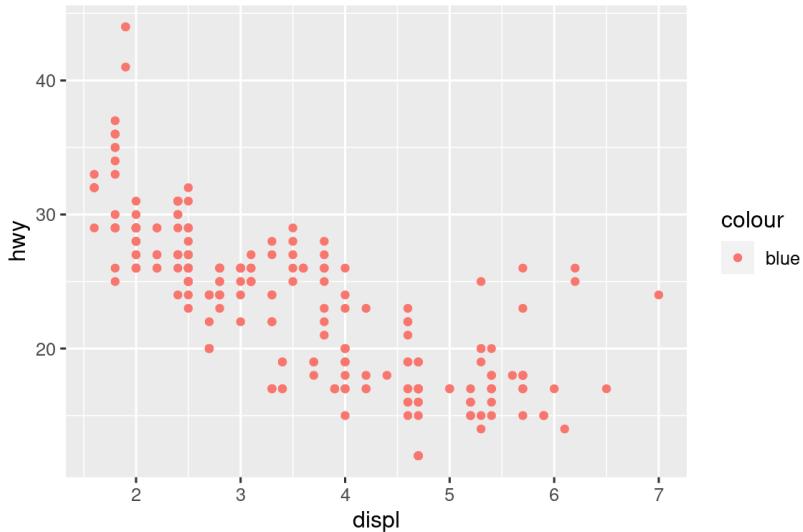

So far we have discussed aesthetics that we can map or set in a scatterplot, when using a point geom. You can learn more about all possible aesthetic mappings in the aesthetic specifications vignette at <https://ggplot2.tidyverse.org/articles/ggplot2-specs.html>.

The specific aesthetics you can use for a plot depend on the geom you use to represent the data. In the next section we dive deeper into geoms.

11.2.1 Exercises

1. Create a scatterplot of `hwy` vs. `displ` where the points are pink filled in triangles.
2. Why did the following code not result in a plot with blue points?

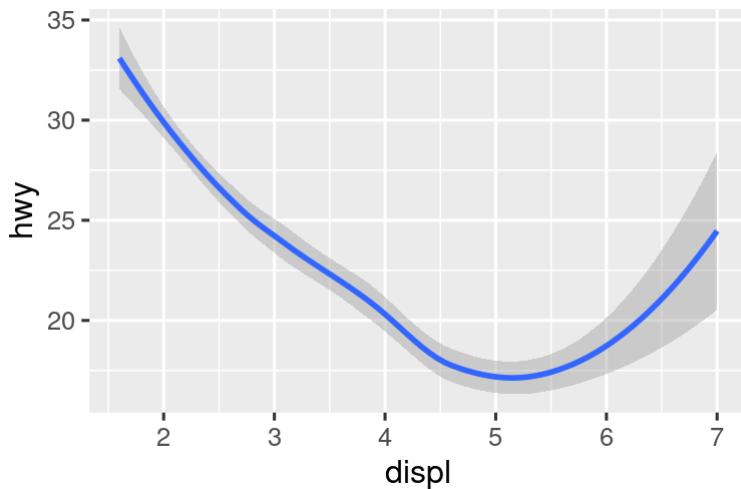

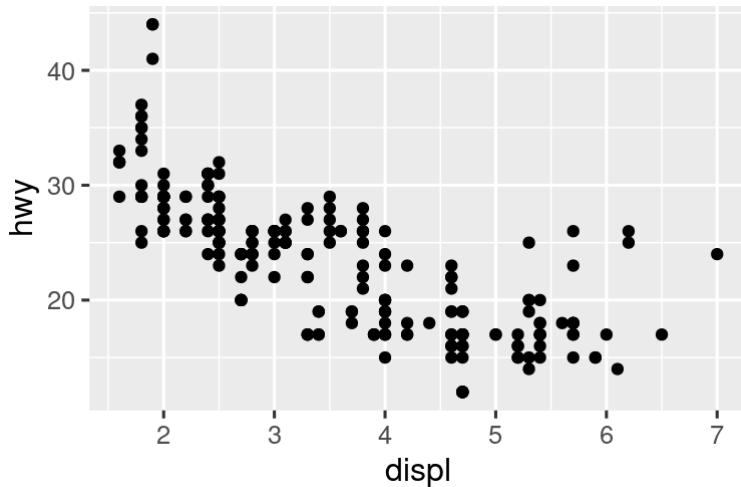

```
ggplot(mpg) +  
  geom_point(aes(x = displ, y = hwy, color = "blue"))
```

3. What does the `stroke` aesthetic do? What shapes does it work with? (Hint: use `?geom_point`)
4. What happens if you map an aesthetic to something other than a variable name, like `aes(color = displ < 5)`? Note, you'll also need to specify x and y.

11.3 Geometric objects

How are these two plots similar?

Both plots contain the same x variable, the same y variable, and both describe the same data. But the plots are not identical. Each plot uses a different geometric object, geom, to represent the data. The plot on the left uses the point geom, and the plot on the right uses the smooth geom, a smooth line fitted to the data.

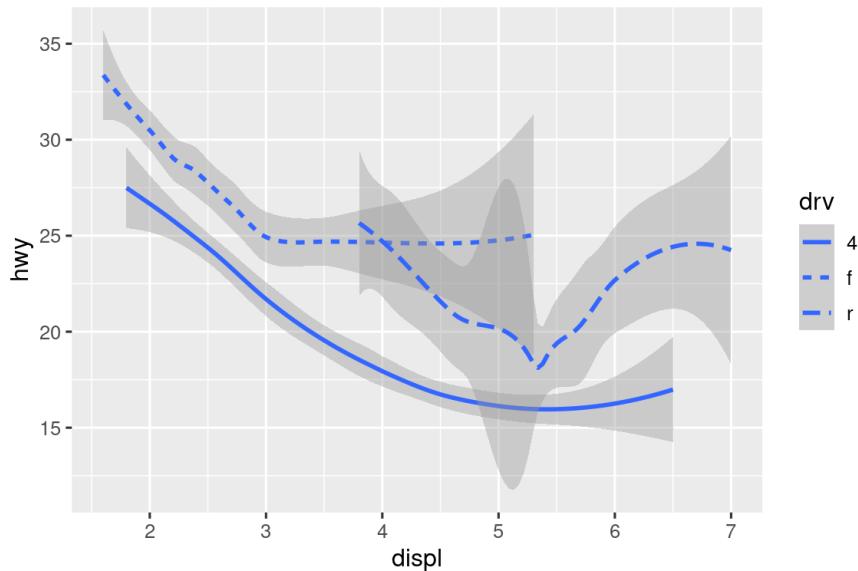

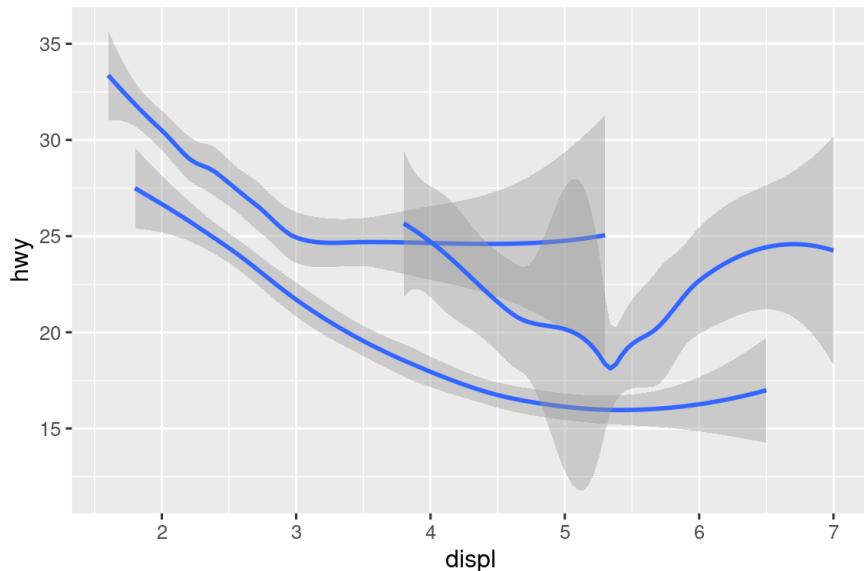

To change the geom in your plot, change the geom function that you add to `ggplot()`. For instance, to make the plots above, you can use

this code:

```
# Left  
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point()  
  
# Right  
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_smooth()
```

Every geom function in ggplot2 takes a `mapping` argument. However, not every aesthetic works with every geom. You could set the shape of a point, but you couldn't set the “shape” of a line. If you try, ggplot2 will silently ignore that aesthetic mapping. On the other hand, you *could* set the linetype of a line. `geom_smooth()` will draw a different line, with a different linetype, for each unique value of the variable that you map to linetype.

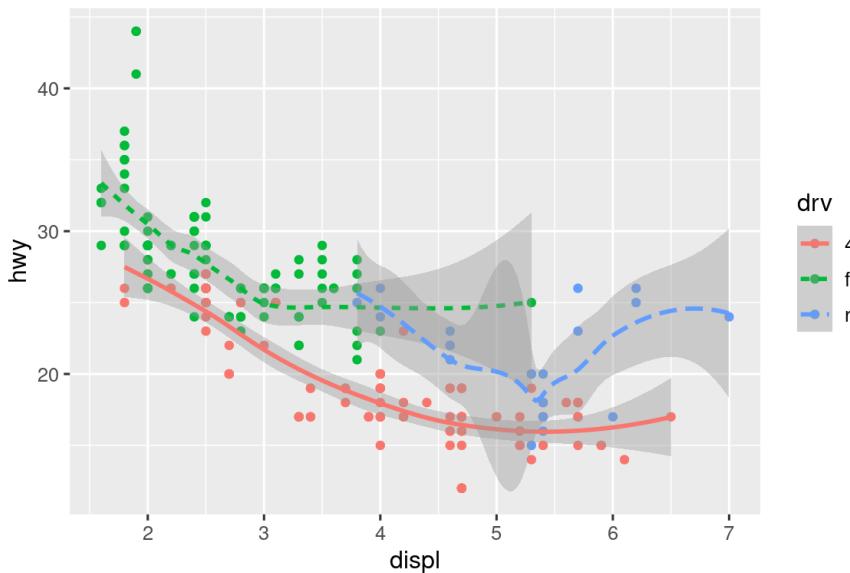

```
ggplot(mpg, aes(x = displ, y = hwy, shape = drv)) +  
  geom_smooth()  
ggplot(mpg, aes(x = displ, y = hwy, linetype = drv)) +  
  geom_smooth()
```

Here, `geom_smooth()` separates the cars into three lines based on their `drv` value, which describes a car's drive train. One line describes all of the points that have a `4` value, one line describes all of the points that have an `f` value, and one line describes all of the points that have an `r`

value. Here, 4 stands for four-wheel drive, f for front-wheel drive, and r for rear-wheel drive.

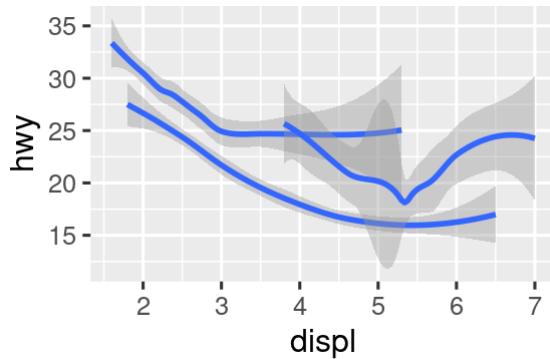

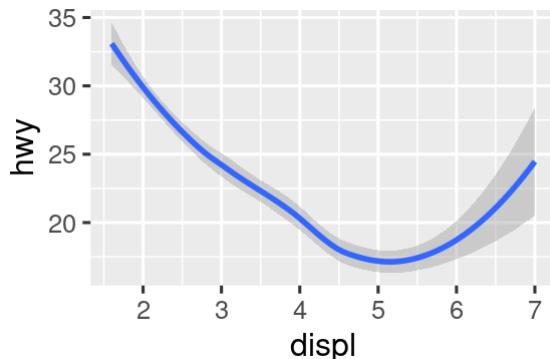

If this sounds strange, we can make it more clear by overlaying the lines on top of the raw data and then coloring everything according to `drv`.

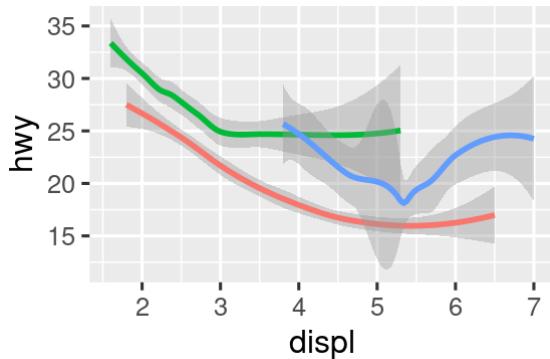

Notice that this plot contains two geoms in the same graph.

Many geoms, like `geom_smooth()`, use a single geometric object to display multiple rows of data. For these geoms, you can set the `group` aesthetic to a categorical variable to draw multiple objects. `ggplot2` will draw a separate object for each unique value of the grouping variable. In practice, `ggplot2` will automatically group the data for these geoms whenever you map an aesthetic to a discrete variable (as in the `linetype` example). It is convenient to rely on this feature because the `group` aesthetic by itself does not add a legend or distinguishing features to the geoms.

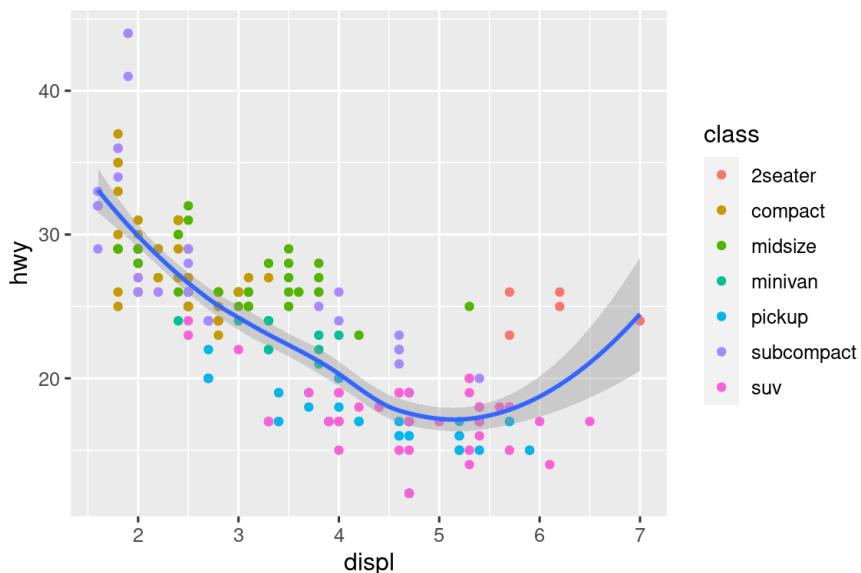

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_smooth()  
  
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_smooth(aes(group = drv))  
  
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_smooth(aes(color = drv), show.legend = FALSE)
```

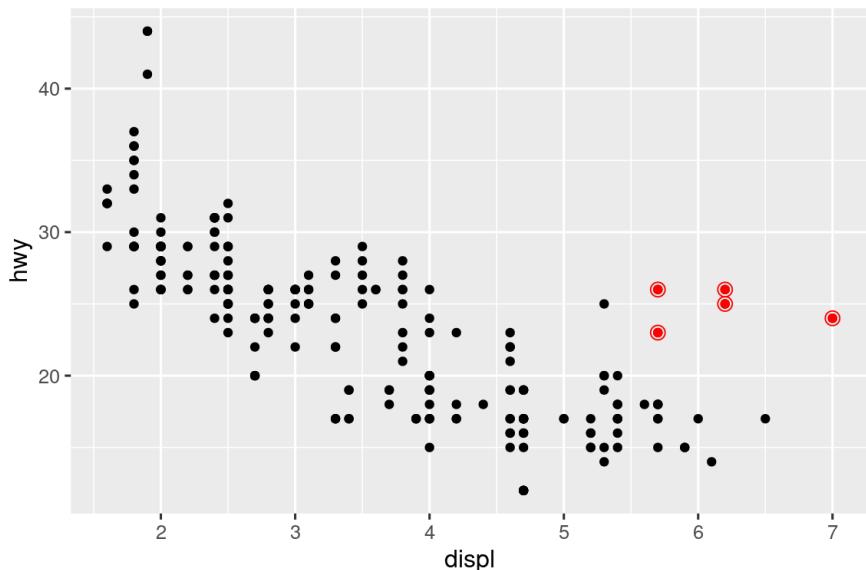

If you place mappings in a `geom` function, `ggplot2` will treat them as local mappings for the layer. It will use these mappings to extend or overwrite the global mappings *for that layer only*. This makes it possible to display different aesthetics in different layers.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class)) +  
  geom_smooth()
```

You can use the same idea to specify different data for each layer. Here, we use red points as well as open circles to highlight two-seater cars. The local data argument in `geom_smooth()` overrides the global data argument in `ggplot()` for that layer only.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  geom_point(  
    data = mpg |> filter(class == "2seater"),  
    color = "red"  
  ) +  
  geom_point(  
    data = mpg |> filter(class == "2seater"),  
    shape = "circle open", size = 3, color = "red"  
  )
```

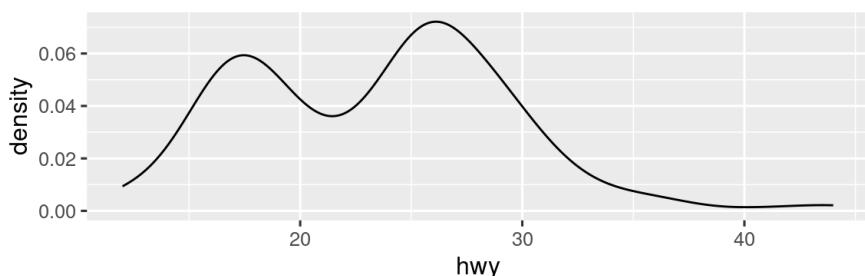

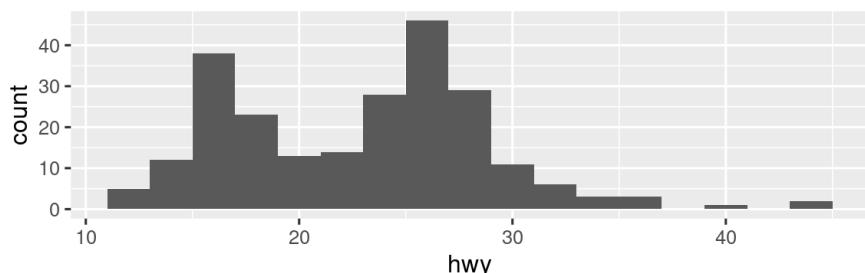

(You'll learn how `filter()` works in the chapter on data transformations: for now, just know that this command selects only the subcompact cars.)

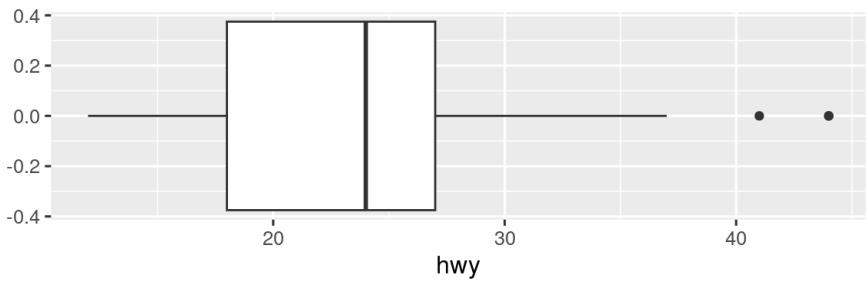

Geoms are the fundamental building blocks of ggplot2. You can completely transform the look of your plot by changing its geom, and different geoms can reveal different features of your data. For example, the histogram and density plot below reveal that the distribution of highway mileage is bimodal and right skewed while the boxplot reveals two potential outliers.

```
# Left
ggplot(mpg, aes(x = hwy)) +
  geom_histogram(binwidth = 2)

# Middle
ggplot(mpg, aes(x = hwy)) +
  geom_density()

# Right
ggplot(mpg, aes(x = hwy)) +
  geom_boxplot()
```

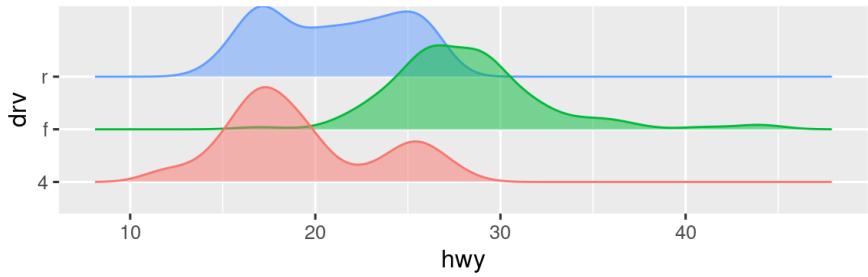

ggplot2 provides more than 40 geoms but these don't cover all possible plots one could make. If you need a different geom, we recommend looking into extension packages first to see if someone else has already implemented it (see <https://exts.ggplot2.tidyverse.org/gallery/> for a sampling). For example, the **ggridges** package (<https://wilkelab.org/ggridges>) is useful for making ridgeline plots, which can be useful for visualizing the density of a numerical variable for different levels of a categorical variable. In the following plot not only did we use a new geom (`geom_density_ridges()`), but we have also mapped the same variable to multiple aesthetics (`drv` to `y`, `fill`, and `color`) as well as set an aesthetic (`alpha = 0.5`) to make the density curves transparent.

```
library(ggridges)
```

```
ggplot(mpg, aes(x = hwy, y = drv, fill = drv, color = drv,
  geom_density_ridges(alpha = 0.5, show.legend = FALSE))
#> Picking joint bandwidth of 1.28
```

The best place to get a comprehensive overview of all of the geoms `ggplot2` offers, as well as all functions in the package, is the reference page: <https://ggplot2.tidyverse.org/reference>. To learn more about any single geom, use the help (e.g. `?geom_smooth`).

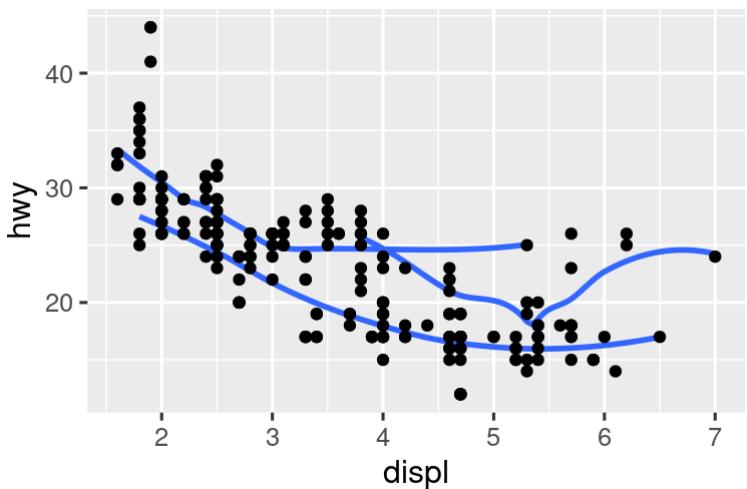

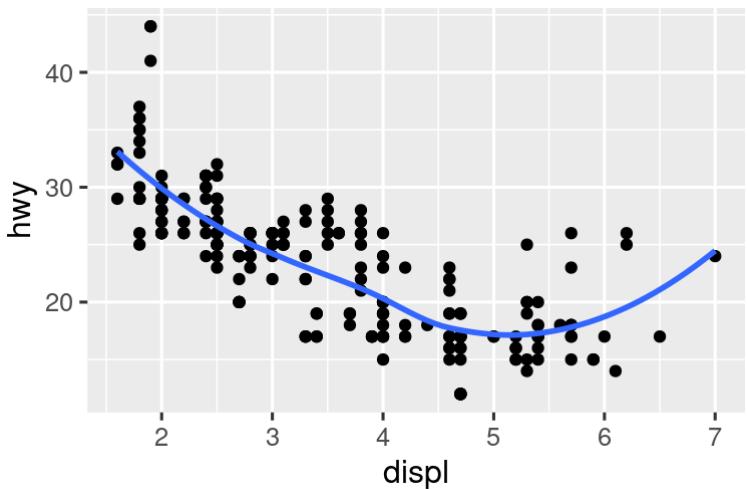

11.3.1 Exercises

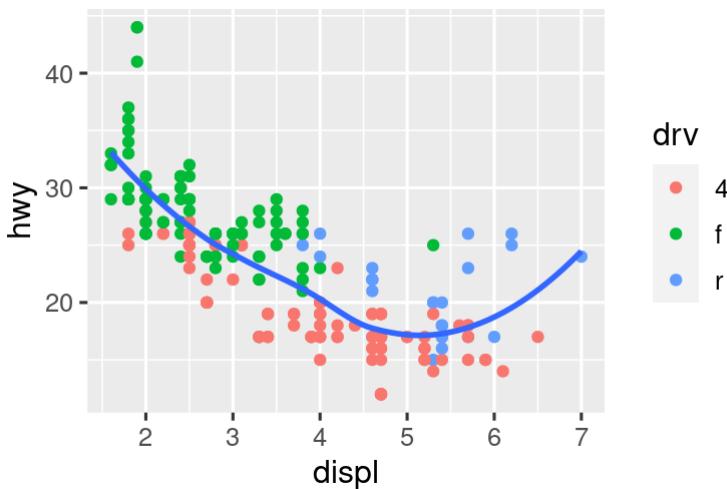

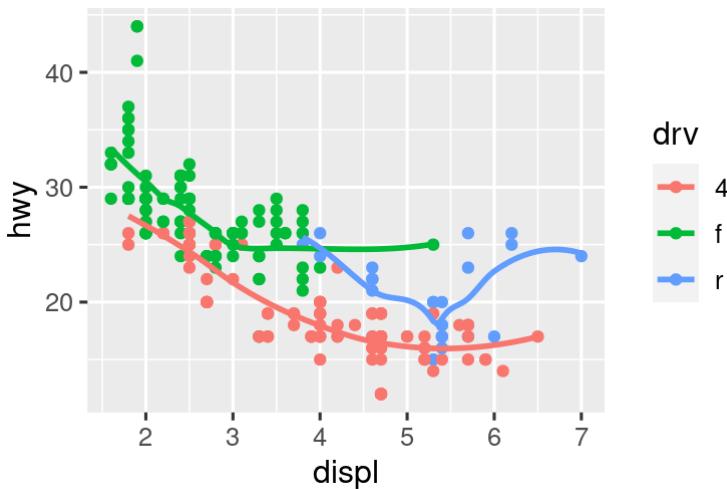

1. What geom would you use to draw a line chart? A boxplot? A histogram? An area chart?
2. Earlier in this chapter we used `show.legend` without explaining it:

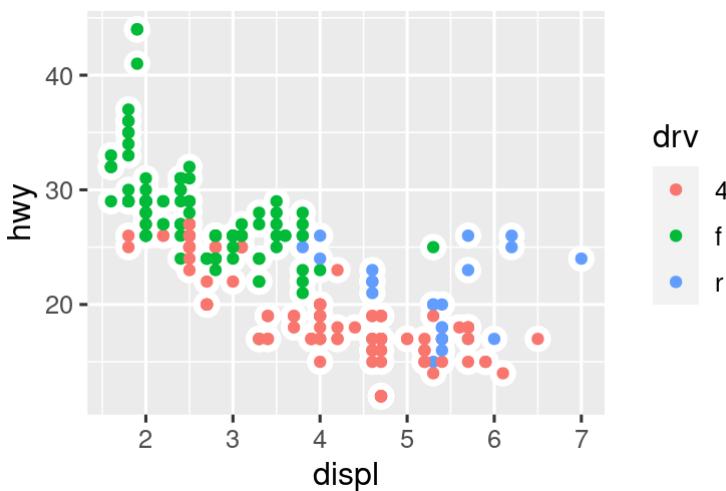

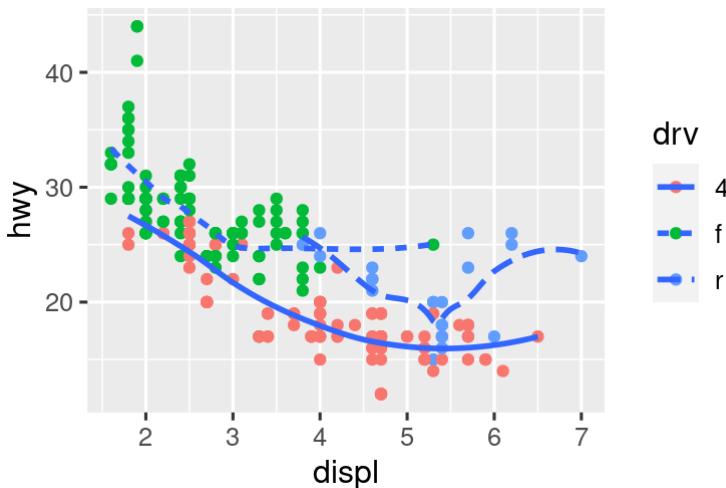

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_smooth(aes(color = drv), show.legend = FALSE)
```

What does `show.legend = FALSE` do here? What happens if you remove it? Why do you think we used it earlier?

3. What does the `se` argument to `geom_smooth()` do?
4. Recreate the R code necessary to generate the following graphs.
Note that wherever a categorical variable is used in the plot, it's `drv`.

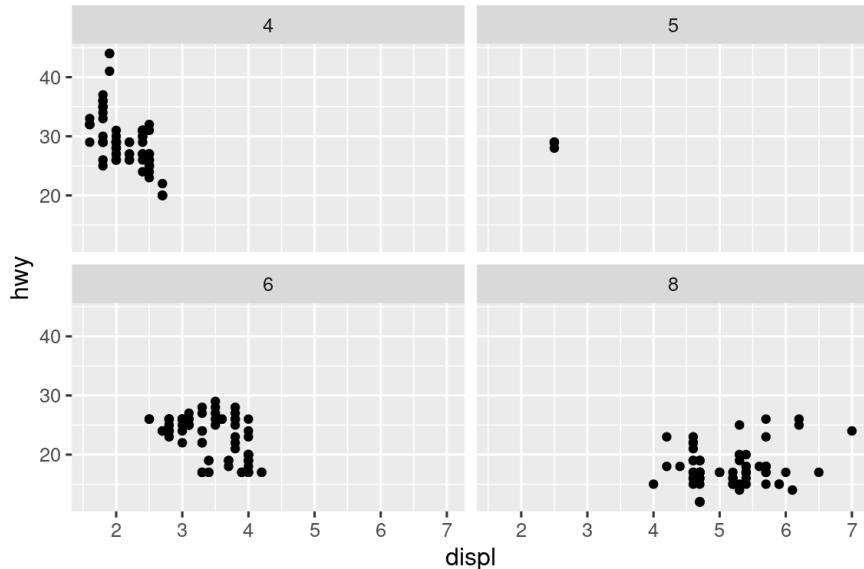

11.4 Facets

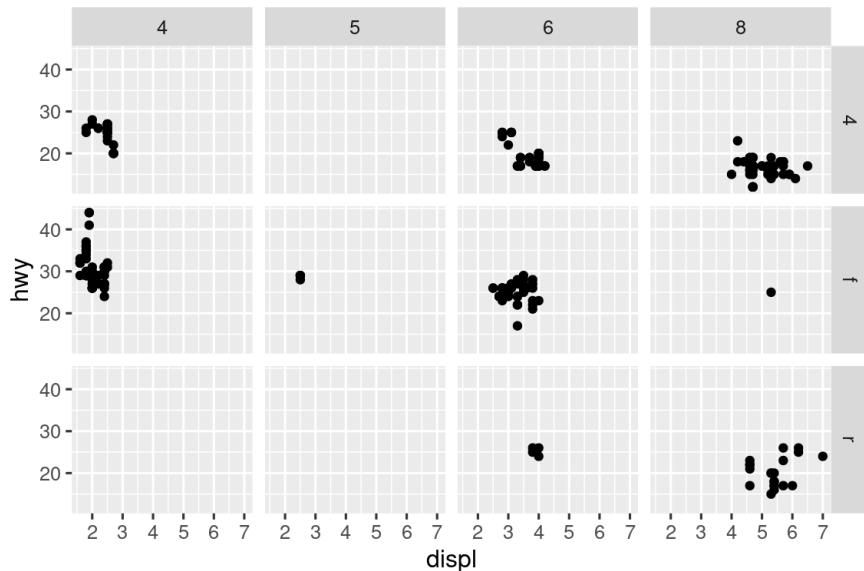

In [Chapter 2](#) you learned about faceting with `facet_wrap()`, which splits a plot into subplots that each display one subset of the data based on a categorical variable.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  facet_wrap(~cyl)
```

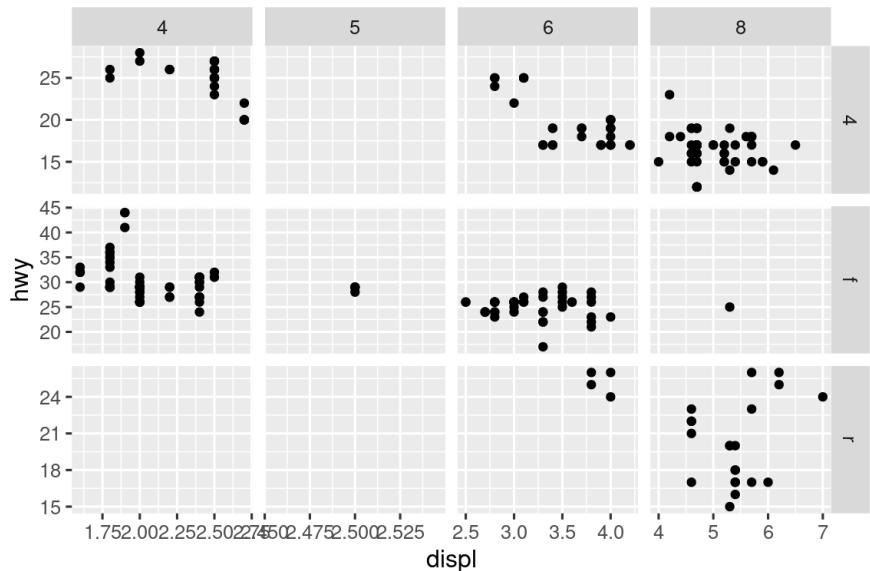

To facet your plot with the combination of two variables, switch from `facet_wrap()` to `facet_grid()`. The first argument of `facet_grid()` is also a formula, but now it's a double sided formula: `rows ~ cols`.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  facet_grid(drv ~ cyl)
```

By default each of the facets share the same scale for x and y axes. This is useful when you want to compare data across facets but it can be limiting when you want to visualize the relationship within each facet better. Setting the `scales` argument in a faceting function to "free" will allow for different axis scales across both rows and columns. Other options for this argument are "free_x" (different scales across rows) and "free_y" (different scales across columns).

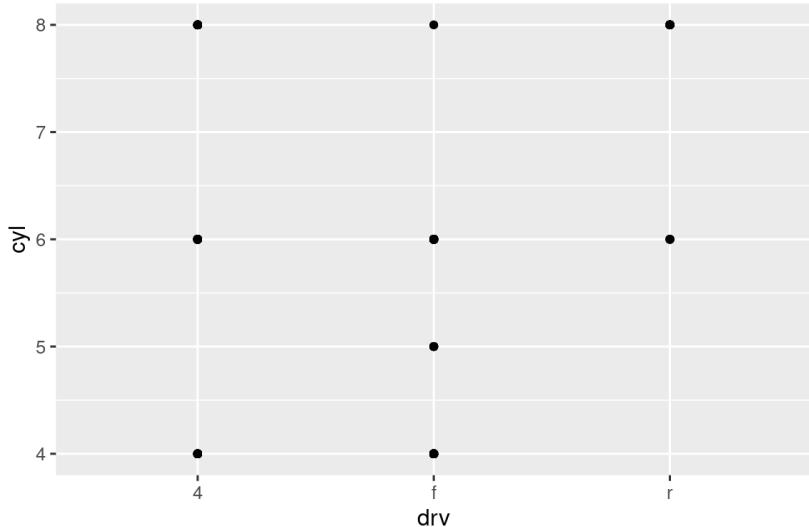

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  facet_grid(drv ~ cyl, scales = "free")
```

11.4.1 Exercises

1. What happens if you facet on a continuous variable?
2. What do the empty cells in plot with `facet_grid(drv ~ cyl)` mean? How do they relate to this plot?

```
ggplot(mpg) +  
  geom_point(aes(x = drv, y = cyl))
```

3. What plots does the following code make? What does `.` do?

```
ggplot(mpg) +  
  geom_point(aes(x = displ, y = hwy)) +  
  facet_grid(drv ~ .)
```

```
ggplot(mpg) +  
  geom_point(aes(x = displ, y = hwy)) +  
  facet_grid(. ~ cyl)
```

4. Take the first faceted plot in this section:

```
ggplot(mpg) +  
  geom_point(aes(x = displ, y = hwy)) +  
  facet_wrap(~ class, nrow = 2)
```

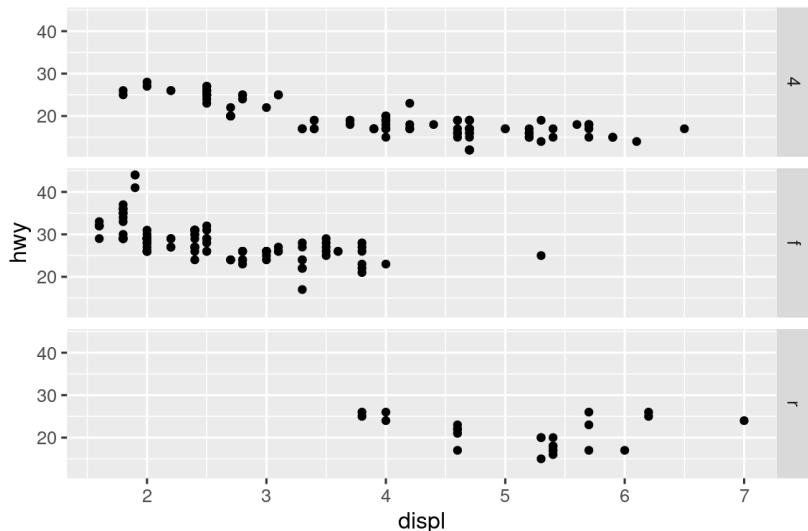

What are the advantages to using facetting instead of the color aesthetic? What are the disadvantages? How might the balance change if you had a larger dataset?

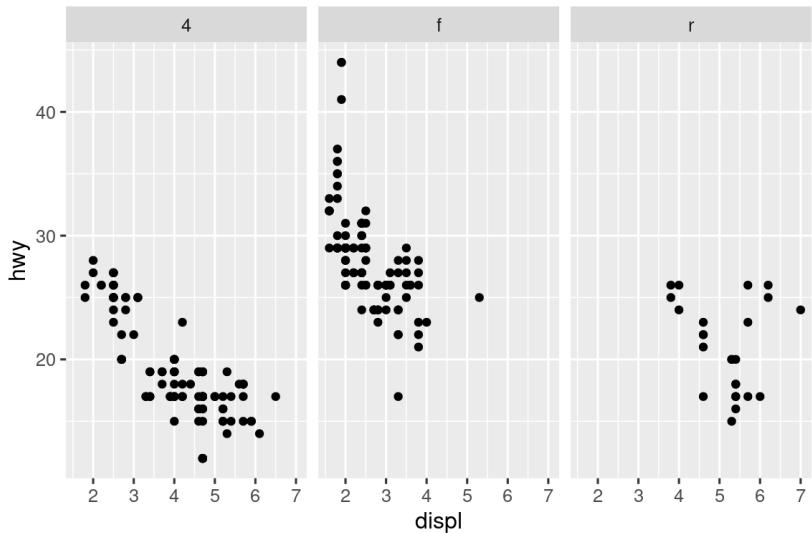

5. Read `?facet_wrap`. What does `nrow` do? What does `ncol` do?

What other options control the layout of the individual panels? Why doesn't `facet_grid()` have `nrow` and `ncol` arguments?

6. Which of the following two plots makes it easier to compare engine size (`displ`) across cars with different drive trains? What does this say about when to place a faceting variable across rows or columns?

```
ggplot(mpg) +  
  geom_point(aes(x = displ, y = hwy)) +  
  facet_grid(drv ~ .)  
  
ggplot(mpg) +  
  geom_point(aes(x = displ, y = hwy)) +  
  facet_grid(. ~ drv)
```

7. Recreate this plot using `facet_wrap()` instead of `facet_grid()`. How do the positions of the facet labels change?

```
ggplot(mpg) +  
  geom_point(aes(x = displ, y = hwy)) +  
  facet_grid(drv ~ .)
```

Scatterplot of highway fuel efficiency versus engine size of cars, faceted by type of drive train across rows.

11.5 Statistical transformations

Consider a basic bar chart, drawn with `geom_bar()` or `geom_col()`. The following chart displays the total number of diamonds in the `diamonds` dataset, grouped by `cut`. The `diamonds` dataset is in the `ggplot2` package and contains information on ~54,000 diamonds, including the `price`, `carat`, `color`, `clarity`, and `cut` of each

diamond. The chart shows that more diamonds are available with high quality cuts than with low quality cuts.

```
ggplot(diamonds, aes(x = cut)) +  
  geom_bar()
```

Bar chart of number of each cut of diamond. There are roughly 1500 Fair, 5000 Good, 12000 Very Good, 14000 Premium, and 22000 Ideal cut diamonds.

On the x-axis, the chart displays `cut`, a variable from `diamonds`. On the y-axis, it displays count, but count is not a variable in `diamonds`! Where does count come from? Many graphs, like scatterplots, plot the raw values of your dataset. Other graphs, like bar charts, calculate new values to plot:

- Bar charts, histograms, and frequency polygons bin your data and then plot bin counts, the number of points that fall in each bin.
- Smoothers fit a model to your data and then plot predictions from the model.
- Boxplots compute a robust summary of the distribution and then display that summary as a specially formatted box.

The algorithm used to calculate new values for a graph is called a **stat**, short for statistical transformation. [Figure 11.2](#) shows how this process works with `geom_bar()`.

A figure demonstrating three steps of creating a bar chart. Step 1. `geom_bar()` begins with the diamonds data set. Step 2. `geom_bar()` transforms the data with the count stat, which returns a data set of cut values and counts. Step 3. `geom_bar()` uses the transformed data to build the plot. `cut` is mapped to the x-axis, `count` is mapped to the y-axis.

Figure 11.2: When create a bar chart we first start with the raw data, then aggregate it to count the number of observations in each bar, and finally map those computed variables to plot aesthetics.

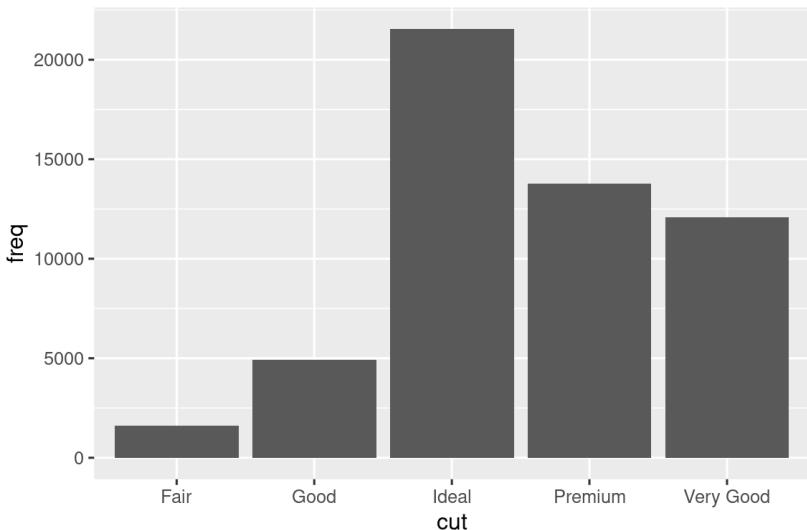

You can learn which stat a geom uses by inspecting the default value for the `stat` argument. For example, `?geom_bar` shows that the default value for `stat` is “count”, which means that `geom_bar()` uses `stat_count()`. `stat_count()` is documented on the same page as `geom_bar()`. If you scroll down, the section called “Computed variables” explains that it computes two new variables: `count` and `prop`.

Every geom has a default stat; and every stat has a default geom. This means that you can typically use geoms without worrying about the underlying statistical transformation. However, there are three reasons why you might need to use a stat explicitly:

1. You might want to override the default stat. In the code below, we change the stat of `geom_bar()` from `count` (the default) to `identity`. This lets us map the height of the bars to the raw values of a `y` variable.

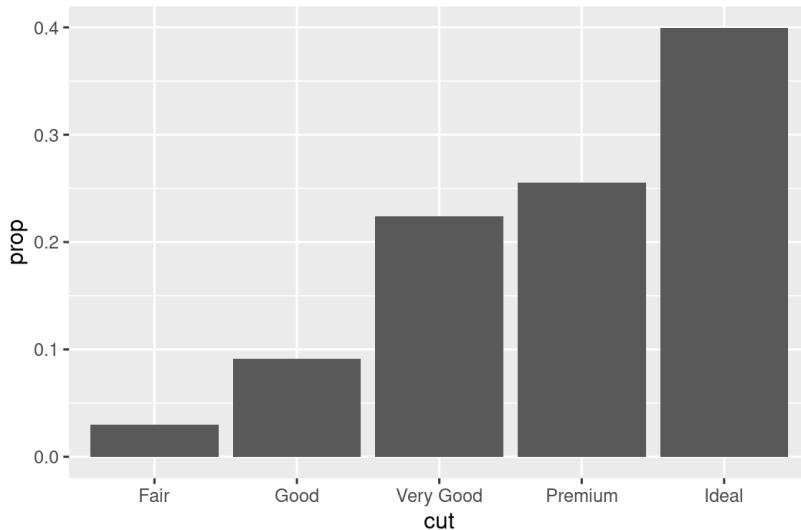

```
cut_frequencies <- tribble(  
  ~cut,           ~freq,  
  "Fair",        1610,  
  "Good",        4906,  
  "Very Good",   12082,  
  "Premium",     13791,  
  "Ideal",       21551  
)
```

```
ggplot(cut_frequencies, aes(x = cut, y = freq)) +  
  geom_bar(stat = "identity")
```

2. You might want to override the default mapping from transformed variables to aesthetics. For example, you might want to display a bar chart of proportions, rather than counts:

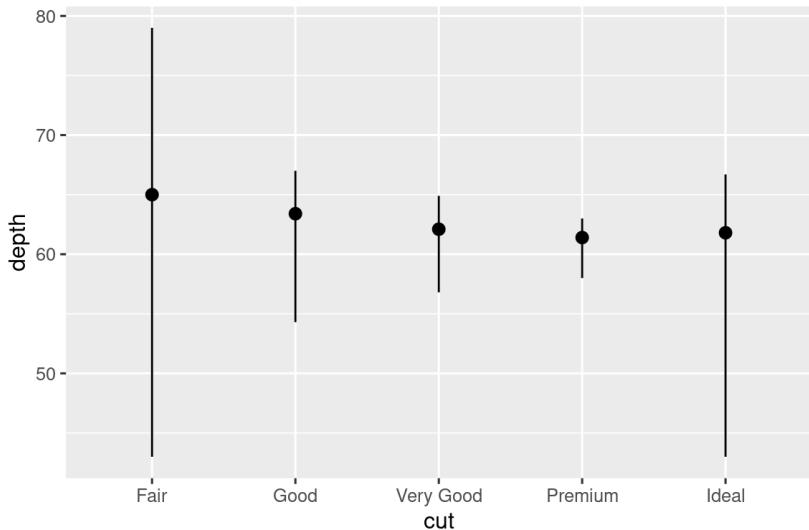

```
ggplot(diamonds, aes(x = cut, y = after_stat(prop)),  
  geom_bar())
```

To find the variables computed by the stat, look for the section titled “computed variables” in the help for `geom_bar()`.

3. You might want to draw greater attention to the statistical transformation in your code. For example, you might use `stat_summary()`, which summarizes the y values for each unique x value, to draw attention to the summary that you’re computing:

```
ggplot(diamonds) +  
  stat_summary(  
    aes(x = cut, y = depth),  
    fun.min = min,  
    fun.max = max,  
    fun = median  
)
```

ggplot2 provides more than 20 stats for you to use. Each stat is a function, so you can get help in the usual way, e.g. `?stat_bin`.

11.5.1 Exercises

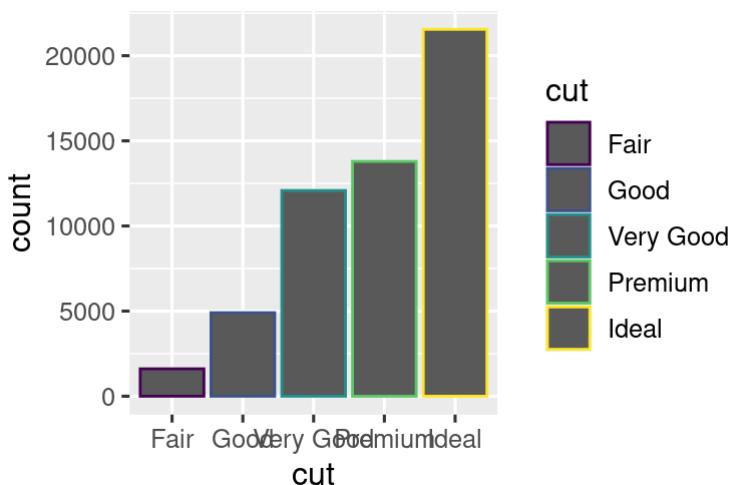

1. What is the default geom associated with `stat_summary()`? How could you rewrite the previous plot to use that geom function instead of the stat function?
2. What does `geom_col()` do? How is it different from `geom_bar()`?
3. Most geoms and stats come in pairs that are almost always used in concert. Read through the documentation and make a list of all the pairs. What do they have in common?
4. What variables does `stat_smooth()` compute? What parameters control its behavior?
5. In our proportion bar chart, we need to set `group = 1`. Why? In other words, what is the problem with these two graphs?

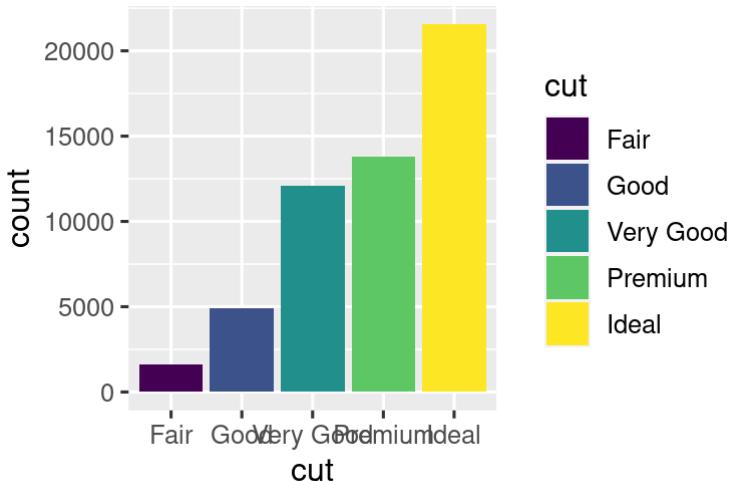

```
ggplot(diamonds, aes(x = cut, y = after_stat(prop)))  
  geom_bar()  
ggplot(diamonds, aes(x = cut, fill = color, y = after_stat(prop)))  
  geom_bar()
```

11.6 Position adjustments

There's one more piece of magic associated with bar charts. You can color a bar chart using either the `color` aesthetic, or, more usefully, `fill`:

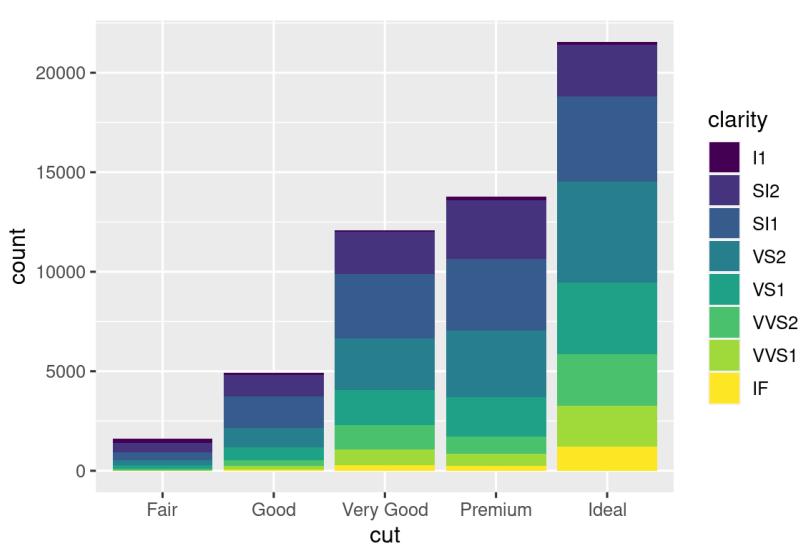

```
ggplot(diamonds, aes(x = cut, color = cut)) +  
  geom_bar()  
ggplot(diamonds, aes(x = cut, fill = cut)) +  
  geom_bar()
```

Note what happens if you map the fill aesthetic to another variable, like `clarity`: the bars are automatically stacked. Each colored rectangle represents a combination of `cut` and `clarity`.

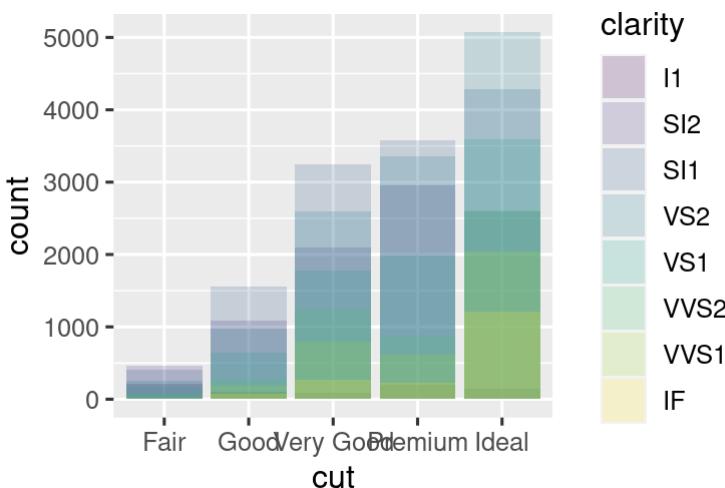

```
ggplot(diamonds, aes(x = cut, fill = clarity)) +  
  geom_bar()
```

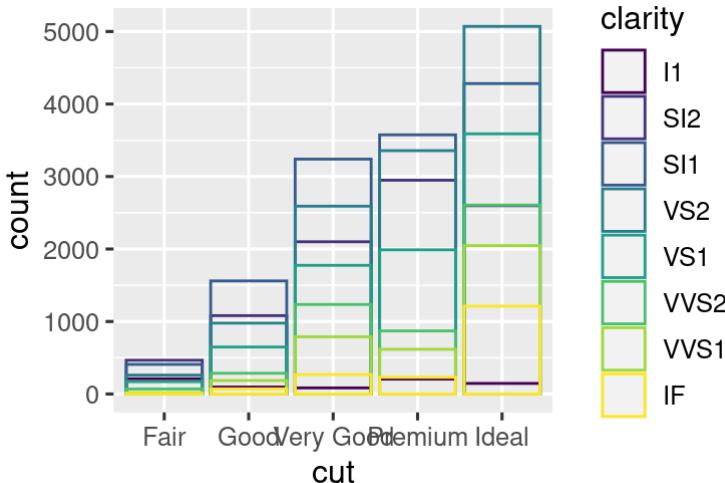

The stacking is performed automatically using the **position adjustment** specified by the `position` argument. If you don't want a stacked bar chart, you can use one of three other options: "identity", "dodge" or "fill".

- `position = "identity"` will place each object exactly where it falls in the context of the graph. This is not very useful for bars, because it overlaps them. To see that overlapping we either need to make the bars slightly transparent by setting `alpha` to a small value, or completely transparent by setting `fill = NA`.

```
ggplot(diamonds, aes(x = cut, fill = clarity)) +
  geom_bar(alpha = 1/5, position = "identity")
ggplot(diamonds, aes(x = cut, color = clarity)) +
  geom_bar(fill = NA, position = "identity")
```

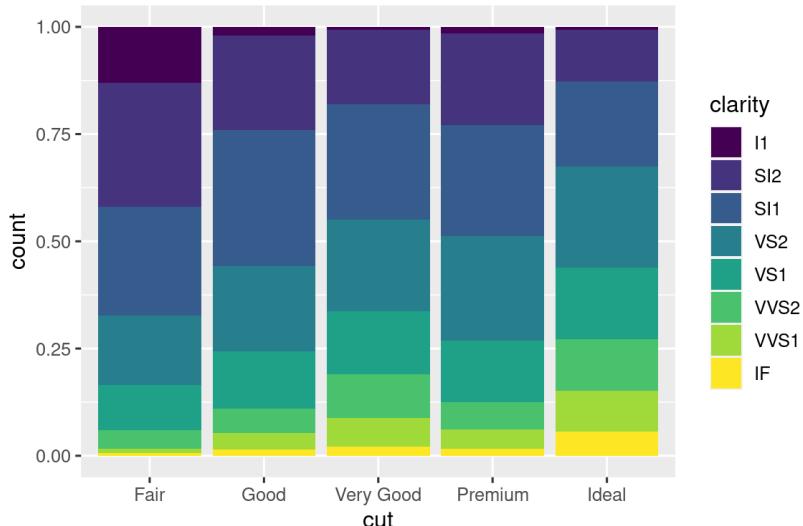

The identity position adjustment is more useful for 2d geoms, like points, where it is the default.

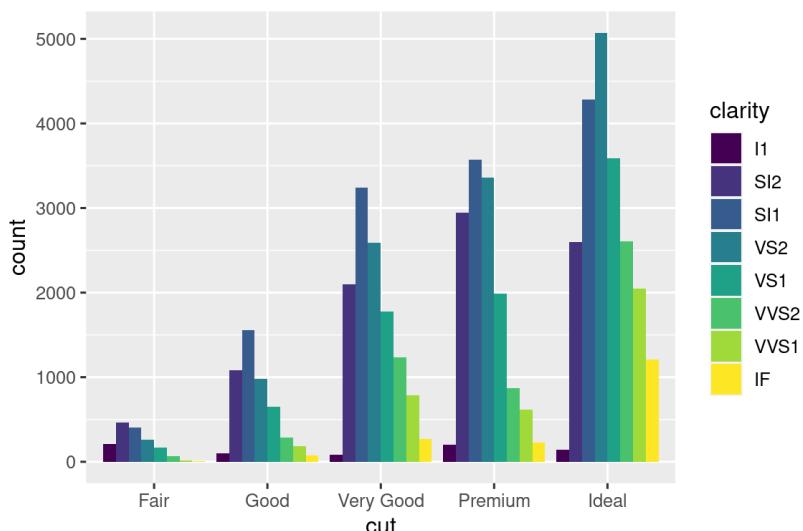

- `position = "fill"` works like stacking, but makes each set of stacked bars the same height. This makes it easier to compare proportions across groups.

```
ggplot(diamonds, aes(x = cut, fill = clarity)) +  
  geom_bar(position = "fill")
```

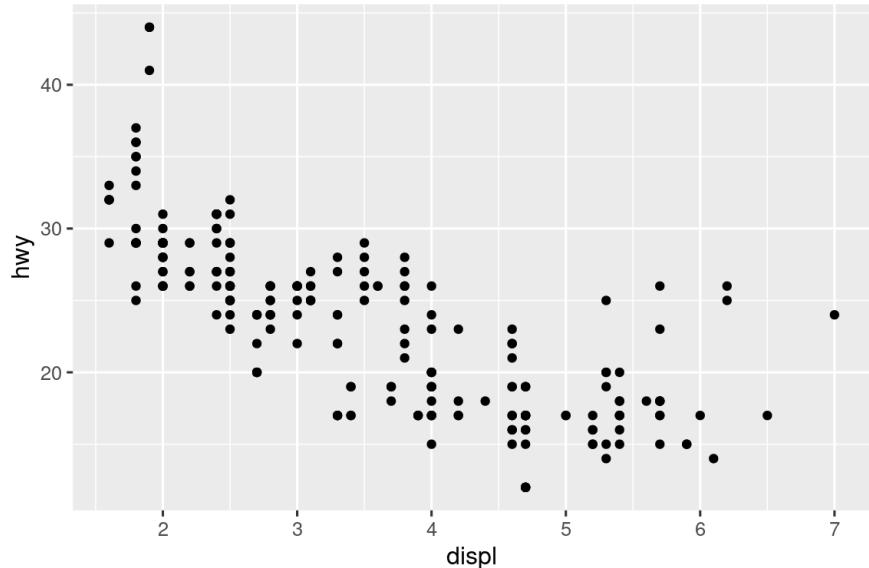

- `position = "dodge"` places overlapping objects directly *beside* one another. This makes it easier to compare individual values.

```
ggplot(diamonds, aes(x = cut, fill = clarity)) +
  geom_bar(position = "dodge")
```

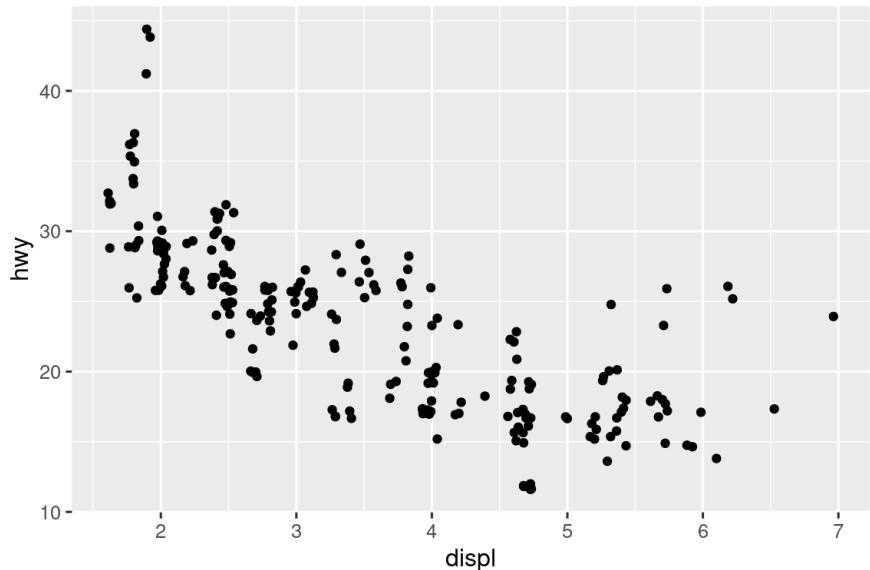

There's one other type of adjustment that's not useful for bar charts, but can be very useful for scatterplots. Recall our first scatterplot. Did you notice that the plot displays only 126 points, even though there are 234 observations in the dataset?

The underlying values of `hwy` and `displ` are rounded so the points appear on a grid and many points overlap each other. This problem is known as **overplotting**. This arrangement makes it difficult to see the distribution of the data. Are the data points spread equally throughout the graph, or is there one special combination of `hwy` and `displ` that contains 109 values?

You can avoid this gridding by setting the position adjustment to "jitter". `position = "jitter"` adds a small amount of random noise to each point. This spreads the points out because no two points are likely to receive the same amount of random noise.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(position = "jitter")
```

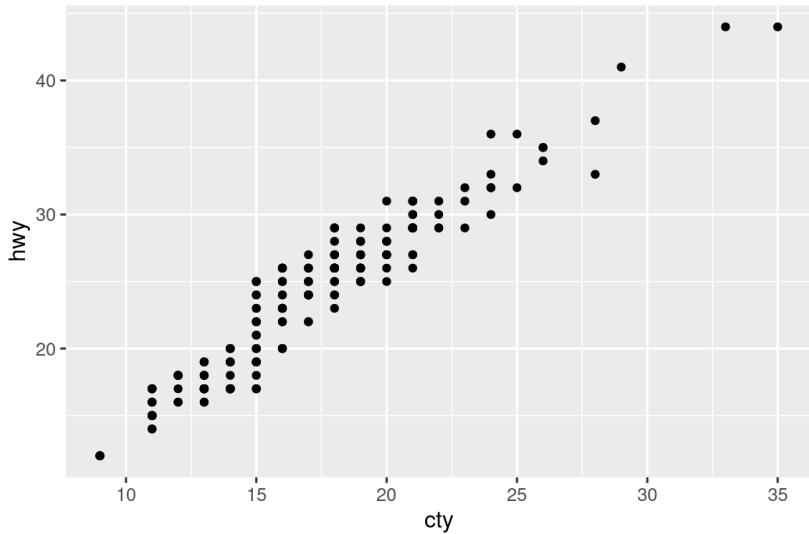

Adding randomness seems like a strange way to improve your plot, but while it makes your graph less accurate at small scales, it makes your graph *more* revealing at large scales. Because this is such a useful operation, ggplot2 comes with a shorthand for `geom_point(position = "jitter") : geom_jitter()`.

To learn more about a position adjustment, look up the help page associated with each adjustment: `?position_dodge`, `?position_fill`, `?position_identity`, `?position_jitter`, and `?position_stack`.

11.6.1 Exercises

1. What is the problem with this plot? How could you improve it?

```
ggplot(mpg, aes(x = cty, y = hwy)) +  
  geom_point()
```

2. What parameters to `geom_jitter()` control the amount of jittering?
3. Compare and contrast `geom_jitter()` with `geom_count()`.
4. What's the default position adjustment for `geom_boxplot()`? Create a visualization of the `mpg` dataset that demonstrates it.

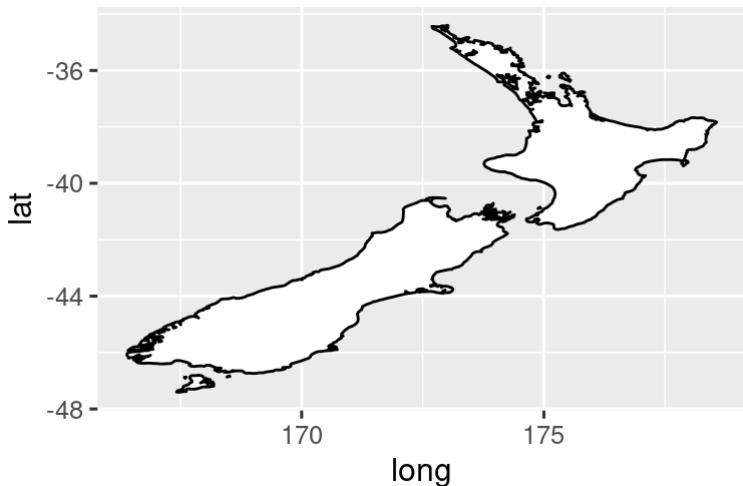

11.7 Coordinate systems

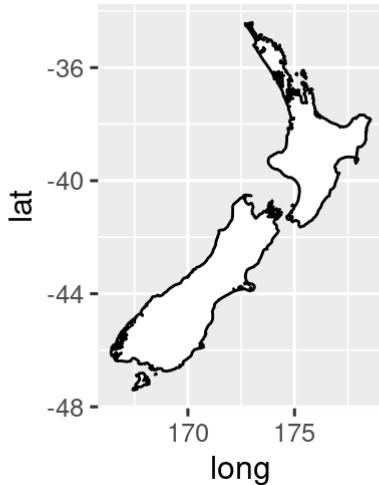

Coordinate systems are probably the most complicated part of ggplot2. The default coordinate system is the Cartesian coordinate system where the x and y positions act independently to determine the location of each point. There are two other coordinate systems that are occasionally helpful.

- `coord_quickmap()` sets the aspect ratio correctly for maps. This is very important if you're plotting spatial data with ggplot2. We don't have the space to discuss maps in this book, but you can

learn more in the [Maps chapter](#) of *ggplot2: Elegant graphics for data analysis*.

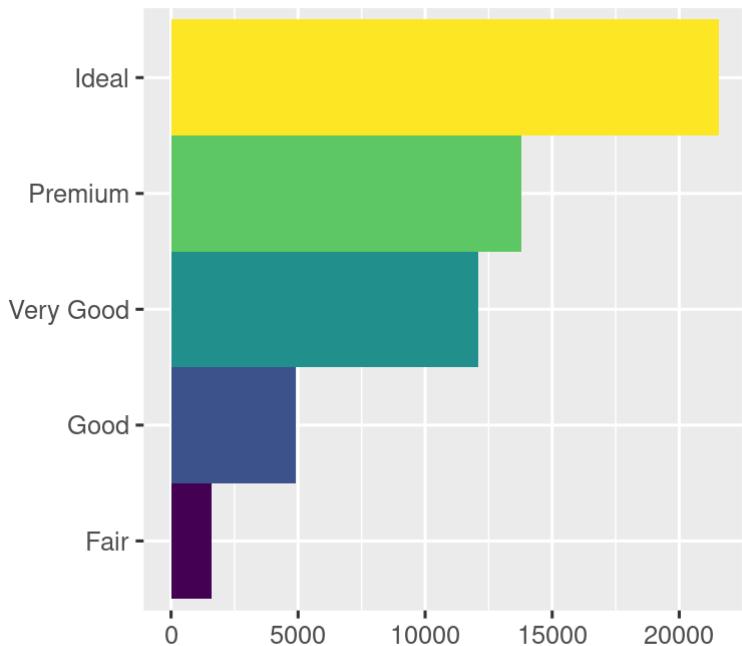

```
nz <- map_data("nz")  
  
ggplot(nz, aes(x = long, y = lat, group = group)) +  
  geom_polygon(fill = "white", color = "black")  
  
ggplot(nz, aes(x = long, y = lat, group = group)) +  
  geom_polygon(fill = "white", color = "black") +  
  coord_quickmap()
```

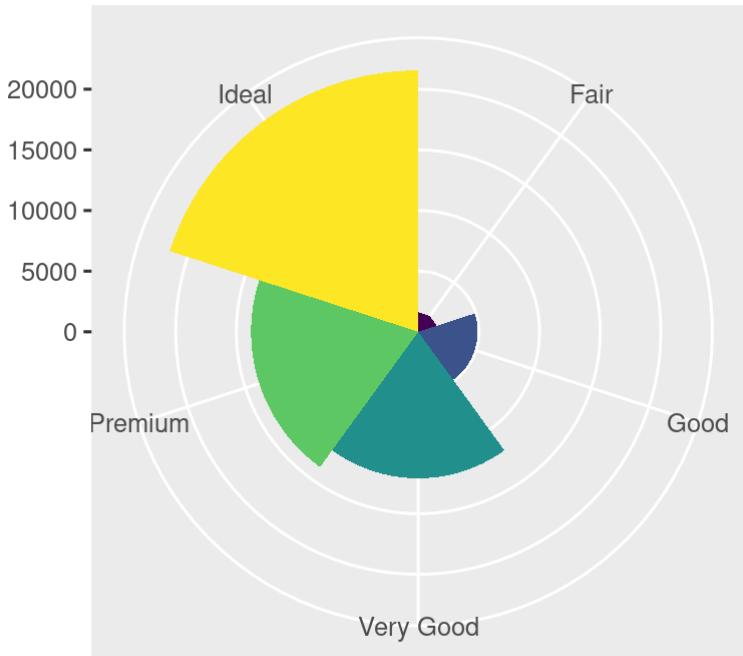

- `coord_polar()` uses polar coordinates. Polar coordinates reveal an interesting connection between a bar chart and a Coxcomb chart.

```
bar <- ggplot(data = diamonds) +  
  geom_bar(  
    mapping = aes(x = cut, fill = cut),  
    show.legend = FALSE,  
    width = 1  
  ) +  
  theme(aspect.ratio = 1) +  
  labs(x = NULL, y = NULL)  
  
bar + coord_flip()  
bar + coord_polar()
```

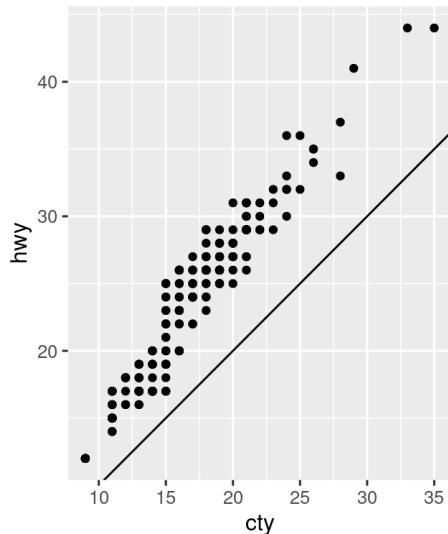

11.7.1 Exercises

1. Turn a stacked bar chart into a pie chart using `coord_polar()`.
2. What's the difference between `coord_quickmap()` and `coord_map()`?
3. What does the plot below tell you about the relationship between city and highway mpg? Why is `coord_fixed()` important? What does `geom_abline()` do?

```
ggplot(data = mpg, mapping = aes(x = cty, y = hwy))  
  geom_point() +
```

```
geom_abline() +  
coord_fixed()
```

11.8 The layered grammar of graphics

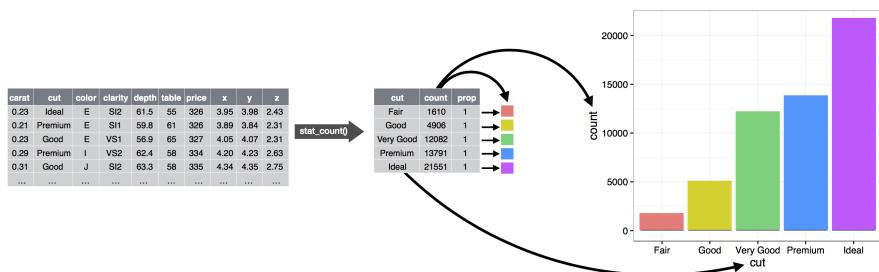

We can expand on the graphing template you learned in [?sec-graphing-template](#) by adding position adjustments, stats, coordinate systems, and faceting:

```
ggplot(data = <DATA>) +  
<GEOM_FUNCTION>(  
  mapping = aes(<MAPPINGS>),  
  stat = <STAT>,  
  position = <POSITION>  
) +  
<COORDINATE_FUNCTION> +  
<FACET_FUNCTION>
```

Our new template takes seven parameters, the bracketed words that appear in the template. In practice, you rarely need to supply all seven parameters to make a graph because ggplot2 will provide useful defaults for everything except the data, the mappings, and the geom function.

The seven parameters in the template compose the grammar of graphics, a formal system for building plots. The grammar of graphics is based on the insight that you can uniquely describe *any* plot as a combination of a dataset, a geom, a set of mappings, a stat, a position adjustment, a coordinate system, and a faceting scheme.

To see how this works, consider how you could build a basic plot from scratch: you could start with a dataset and then transform it into the information that you want to display (with a stat). Next, you could choose a geometric object to represent each observation in the transformed data. You could then use the aesthetic properties of the geoms to represent variables in the data. You would map the values of each variable to the levels of an aesthetic. You'd then select a coordinate system to place the geoms into, using the location of the objects (which is itself an aesthetic property) to display the values of the x and y variables.

At this point, you would have a complete graph, but you could further adjust the positions of the geoms within the coordinate system (a position adjustment) or split the graph into subplots (faceting). You

could also extend the plot by adding one or more additional layers, where each additional layer uses a dataset, a geom, a set of mappings, a stat, and a position adjustment.

You could use this method to build *any* plot that you imagine. In other words, you can use the code template that you've learned in this chapter to build hundreds of thousands of unique plots.

If you'd like to learn more about the theoretical underpinnings of ggplot2, you might enjoy reading "[The Layered Grammar of Graphics](#)", the scientific paper that describes the theory of ggplot2 in detail.

11.9 Summary

In this chapter you learned about the layered grammar of graphics starting with aesthetics and geometries to build a simple plot, facets for splitting the plot into subsets, statistics for understanding how geoms are calculated, position adjustments for controlling the fine details of position when geoms might otherwise overlap, and coordinate systems allow you fundamentally change what `x` and `y` mean. One layer we have not yet touched on is theme, which we will introduce in [Section 13.5](#).

Two very useful resources for getting an overview of the complete ggplot2 functionality are the ggplot2 cheatsheet (which you can find at <https://posit.co/resources/cheatsheets>) and the ggplot2 package website (<https://ggplot2.tidyverse.org>).

An important lesson you should take from this chapter is that when you feel the need for a geom that is not provided by ggplot2, it's always a good idea to look into whether someone else has already solved your problem by creating a ggplot2 extension package that offers that geom.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built
with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter is largely complete and just needs final proof reading. You can find the complete first edition at <https://r4ds.had.co.nz>.

12.1 Introduction

This chapter will show you how to use visualization and transformation to explore your data in a systematic way, a task that statisticians call exploratory data analysis, or EDA for short. EDA is an iterative cycle. You:

1. Generate questions about your data.
2. Search for answers by visualizing, transforming, and modelling your data.
3. Use what you learn to refine your questions and/or generate new questions.

EDA is not a formal process with a strict set of rules. More than anything, EDA is a state of mind. During the initial phases of EDA you should feel free to investigate every idea that occurs to you. Some of these ideas will pan out, and some will be dead ends. As your exploration continues, you will home in on a few particularly productive areas that you'll eventually write up and communicate to others.

EDA is an important part of any data analysis, even if the questions are handed to you on a platter, because you always need to investigate the quality of your data. Data cleaning is just one application of EDA: you ask

questions about whether your data meets your expectations or not. To do data cleaning, you'll need to deploy all the tools of EDA: visualization, transformation, and modelling.

12.1.1 Prerequisites

In this chapter we'll combine what you've learned about dplyr and ggplot2 to interactively ask questions, answer them with data, and then ask new questions.

```
library(tidyverse)
```

12.2 Questions

“There are no routine statistical questions, only questionable statistical routines.” — Sir David Cox

“Far better an approximate answer to the right question, which is often vague, than an exact answer to the wrong question, which can always be made precise.” — John Tukey

Your goal during EDA is to develop an understanding of your data. The easiest way to do this is to use questions as tools to guide your investigation. When you ask a question, the question focuses your attention on a specific part of your dataset and helps you decide which graphs, models, or transformations to make.

EDA is fundamentally a creative process. And like most creative processes, the key to asking *quality* questions is to generate a large *quantity* of questions. It is difficult to ask revealing questions at the start of your analysis because you do not know what insights can be gleaned

from your dataset. On the other hand, each new question that you ask will expose you to a new aspect of your data and increase your chance of making a discovery. You can quickly drill down into the most interesting parts of your data—and develop a set of thought-provoking questions—if you follow up each question with a new question based on what you find.

There is no rule about which questions you should ask to guide your research. However, two types of questions will always be useful for making discoveries within your data. You can loosely word these questions as:

1. What type of variation occurs within my variables?
2. What type of covariation occurs between my variables?

The rest of this chapter will look at these two questions. We'll explain what variation and covariation are, and we'll show you several ways to answer each question. To make the discussion easier, let's define some terms:

- A **variable** is a quantity, quality, or property that you can measure.
- A **value** is the state of a variable when you measure it. The value of a variable may change from measurement to measurement.
- An **observation** is a set of measurements made under similar conditions (you usually make all of the measurements in an observation at the same time and on the same object). An observation will contain several values, each associated with a different variable. We'll sometimes refer to an observation as a data point.
- **Tabular data** is a set of values, each associated with a variable and an observation. Tabular data is *tidy* if each value is placed in its own

“cell”, each variable in its own column, and each observation in its own row.

So far, all of the data that you’ve seen has been tidy. In real-life, most data isn’t tidy, so we’ll come back to these ideas again in [Chapter 25](#).

12.3 Variation

Variation is the tendency of the values of a variable to change from measurement to measurement. You can see variation easily in real life; if you measure any continuous variable twice, you will get two different results. This is true even if you measure quantities that are constant, like the speed of light. Each of your measurements will include a small amount of error that varies from measurement to measurement.

Variables can also vary if you measure across different subjects (e.g. the eye colors of different people) or different times (e.g. the energy levels of an electron at different moments). Every variable has its own pattern of variation, which can reveal interesting information about how that variable varies between measurements on the same observation as well as across observations. The best way to understand that pattern is to visualize the distribution of the variable’s values, which you’ve learned about in [Chapter 2](#).

We’ll start our exploration by visualizing the distribution of weights (`carat`) of ~54,000 diamonds from the `diamonds` dataset. Since `carat` is a numerical variable, we can use a histogram:

```
ggplot(diamonds, aes(x = carat)) +  
  geom_histogram(binwidth = 0.5)
```

A histogram of carats of diamonds, with the x-axis ranging from 0 to 4.5 and the y-axis ranging from 0 to 30000. The distribution is right skewed with very few diamonds in the bin centered at 0, almost 30000 diamonds in the bin centered at 0.5, approximately 15000 diamonds in the bin centered at 1, and much fewer, approximately 5000 diamonds in the bin centered at 1.5. Beyond this, there's a trailing tail.

Now that you can visualize variation, what should you look for in your plots? And what type of follow-up questions should you ask? We've put together a list below of the most useful types of information that you will find in your graphs, along with some follow-up questions for each type of information. The key to asking good follow-up questions will be to rely on your curiosity (What do you want to learn more about?) as well as your skepticism (How could this be misleading?).

12.3.1 Typical values

In both bar charts and histograms, tall bars show the common values of a variable, and shorter bars show less-common values. Places that do not have bars reveal values that were not seen in your data. To turn this information into useful questions, look for anything unexpected:

- Which values are the most common? Why?
- Which values are rare? Why? Does that match your expectations?
- Can you see any unusual patterns? What might explain them?

As an example, the histogram below suggests several interesting questions:

- Why are there more diamonds at whole carats and common fractions of carats?

- Why are there more diamonds slightly to the right of each peak than there are slightly to the left of each peak?

```
smaller <- diamonds |>
  filter(carat < 3)

ggplot(smaller, aes(x = carat)) +
  geom_histogram(binwidth = 0.01)
```

A histogram of carats of diamonds, with the x-axis ranging from 0 to 3 and the y-axis ranging from 0 to roughly 2500. The binwidth is quite narrow (0.01), resulting in a very large number of skinny bars. The distribution is right skewed, with many peaks followed by bars in decreasing heights, until a sharp increase at the next peak.

Clusters of similar values suggest that subgroups exist in your data. To understand the subgroups, ask:

- How are the observations within each cluster similar to each other?
- How are the observations in separate clusters different from each other?
- How can you explain or describe the clusters?
- Why might the appearance of clusters be misleading?

The histogram below shows the length (in minutes) of 272 eruptions of the Old Faithful Geyser in Yellowstone National Park. Eruption times appear to be clustered into two groups: there are short eruptions (of around 2 minutes) and long eruptions (4-5 minutes), but little in between.

```
ggplot(faithful, aes(x = eruptions)) +
  geom_histogram(binwidth = 0.25)
```

 A histogram of eruption times. The x-axis ranges from roughly 1.5 to 5, and the y-axis ranges from 0 to roughly 40. The distribution is bimodal with peaks around 1.75 and 4.5.

Many of the questions above will prompt you to explore a relationship *between* variables, for example, to see if the values of one variable can explain the behavior of another variable. We'll get to that shortly.

12.3.2 Unusual values

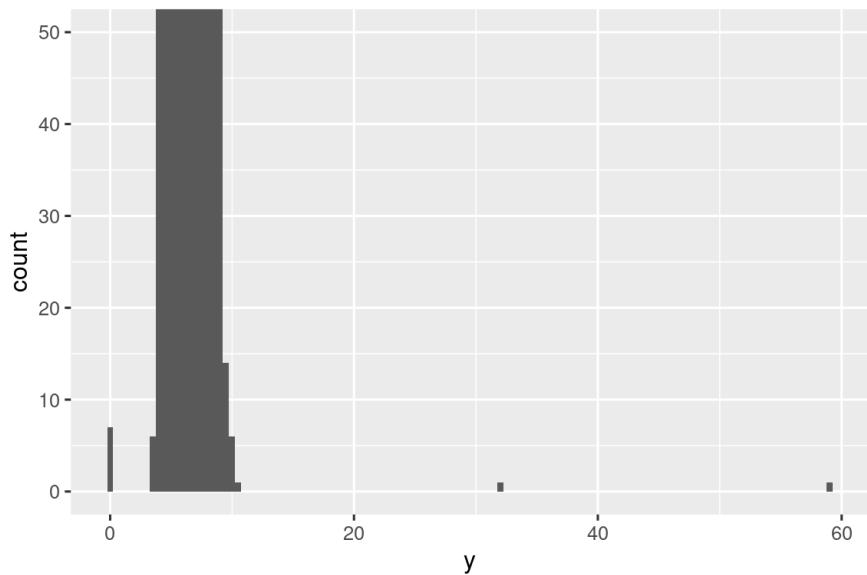

Outliers are observations that are unusual; data points that don't seem to fit the pattern. Sometimes outliers are data entry errors; other times outliers suggest important new science. When you have a lot of data, outliers are sometimes difficult to see in a histogram. For example, take the distribution of the `y` variable from the diamonds dataset. The only evidence of outliers is the unusually wide limits on the x-axis.

```
ggplot(diamonds, aes(x = y)) +  
  geom_histogram(binwidth = 0.5)
```

There are so many observations in the common bins that the rare bins are very short, making it very difficult to see them (although maybe if you stare intently at 0 you'll spot something). To make it easy to see the unusual values, we need to zoom to small values of the y-axis with `coord_cartesian()`:

```
ggplot(diamonds, aes(x = y)) +  
  geom_histogram(binwidth = 0.5) +  
  coord_cartesian(ylim = c(0, 50))
```

`coord_cartesian()` also has an `xlim()` argument for when you need to zoom into the x-axis. `ggplot2` also has `xlim()` and `ylim()` functions that work slightly differently: they throw away the data outside the limits.

This allows us to see that there are three unusual values: 0, ~30, and ~60. We pluck them out with `dplyr`:

```
unusual <- diamonds |>
  filter(y < 3 | y > 20) |>
  select(price, x, y, z) |>
  arrange(y)

unusual
#> # A tibble: 9 × 4
#>   price     x     y     z
#>   <int> <dbl> <dbl> <dbl>
#> 1 5139     0     0     0
#> 2 6381     0     0     0
#> 3 12800    0     0     0
#> 4 15686    0     0     0
#> 5 18034    0     0     0
#> 6 2130     0     0     0
#> 7 2130     0     0     0
#> 8 2075  5.15  31.8  5.12
#> 9 12210  8.09  58.9  8.06
```

The `y` variable measures one of the three dimensions of these diamonds, in mm. We know that diamonds can't have a width of 0mm, so these values must be incorrect. We might also suspect that measurements of 32mm and 59mm are implausible: those diamonds are over an inch long, but don't cost hundreds of thousands of dollars!

It's good practice to repeat your analysis with and without the outliers. If they have minimal effect on the results, and you can't figure out why they're there, it's reasonable to omit them, and move on. However, if they have a substantial effect on your results, you shouldn't drop them without justification. You'll need to figure out what caused them (e.g. a data entry error) and disclose that you removed them in your write-up.

12.3.3 Exercises

1. Explore the distribution of each of the `x`, `y`, and `z` variables in `diamonds`. What do you learn? Think about a diamond and how you might decide which dimension is the length, width, and depth.
2. Explore the distribution of `price`. Do you discover anything unusual or surprising? (Hint: Carefully think about the `binwidth` and make sure you try a wide range of values.)
3. How many diamonds are 0.99 carat? How many are 1 carat? What do you think is the cause of the difference?
4. Compare and contrast `coord_cartesian()` vs. `xlim()` or `ylim()` when zooming in on a histogram. What happens if you leave `binwidth` unset? What happens if you try and zoom so only half a bar shows?

12.4 Unusual values

If you've encountered unusual values in your dataset, and simply want to move on to the rest of your analysis, you have two options.

1. Drop the entire row with the strange values:

```
diamonds2 <- diamonds |>  
  filter(between(y, 3, 20))
```

We don't recommend this option because just because one measurement is invalid, doesn't mean all the measurements are. Additionally, if you have low quality data, by time that you've applied this approach to every variable you might find that you don't have any data left!

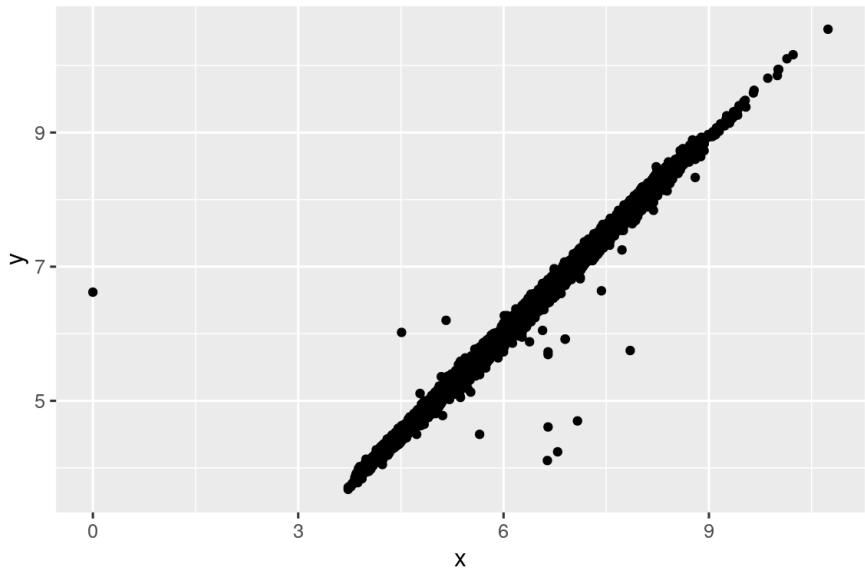

2. Instead, we recommend replacing the unusual values with missing values. The easiest way to do this is to use `mutate()` to replace the variable with a modified copy. You can use the `if_else()` function to replace unusual values with NA :

```
diamonds2 <- diamonds |>  
  mutate(y = if_else(y < 3 | y > 20, NA, y))
```

`if_else()` has three arguments. The first argument `test` should be a logical vector. The result will contain the value of the second argument, `yes`, when `test` is `TRUE`, and the value of the third argument, `no`, when it is false. Alternatively to `if_else()`, use `case_when()`. `case_when()` is particularly useful inside `mutate` when you want to create a new variable that relies on a complex combination of existing variables or would otherwise require multiple `if_else()` statements nested inside one another. You will learn more about logical vectors in [Chapter 14](#).

It's not obvious where you should plot missing values, so `ggplot2` doesn't include them in the plot, but it does warn that they've been removed:

```
ggplot(diamonds2, aes(x = x, y = y)) +  
  geom_point()  
#> Warning: Removed 9 rows containing missing values ('`g
```

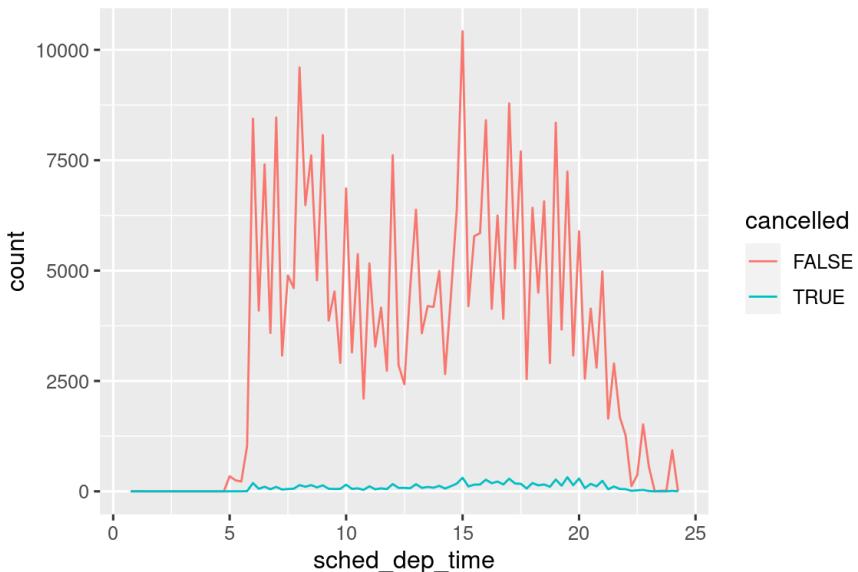

To suppress that warning, set `na.rm = TRUE`:

```
ggplot(diamonds2, aes(x = x, y = y)) +  
  geom_point(na.rm = TRUE)
```

Other times you want to understand what makes observations with missing values different to observations with recorded values. For example, in `nycflights13::flights`¹, missing values in the `dep_time` variable indicate that the flight was cancelled. So you might want to compare the scheduled departure times for cancelled and non-cancelled times. You can do this by making a new variable with `is.na()`.

```
nycflights13::flights |>  
  mutate(  
    cancelled = is.na(dep_time),  
    sched_hour = sched_dep_time %/% 100,  
    sched_min = sched_dep_time %% 100,  
    sched_dep_time = sched_hour + (sched_min / 60)
```

```
) |>  
ggplot(aes(x = sched_dep_time)) +  
geom_freqpoly(aes(color = cancelled), binwidth = 1/4)
```

However this plot isn't great because there are many more non-cancelled flights than cancelled flights. In the next section we'll explore some techniques for improving this comparison.

12.4.1 Exercises

1. What happens to missing values in a histogram? What happens to missing values in a bar chart? Why is there a difference in how missing values are handled in histograms and bar charts?
2. What does `na.rm = TRUE` do in `mean()` and `sum()`?

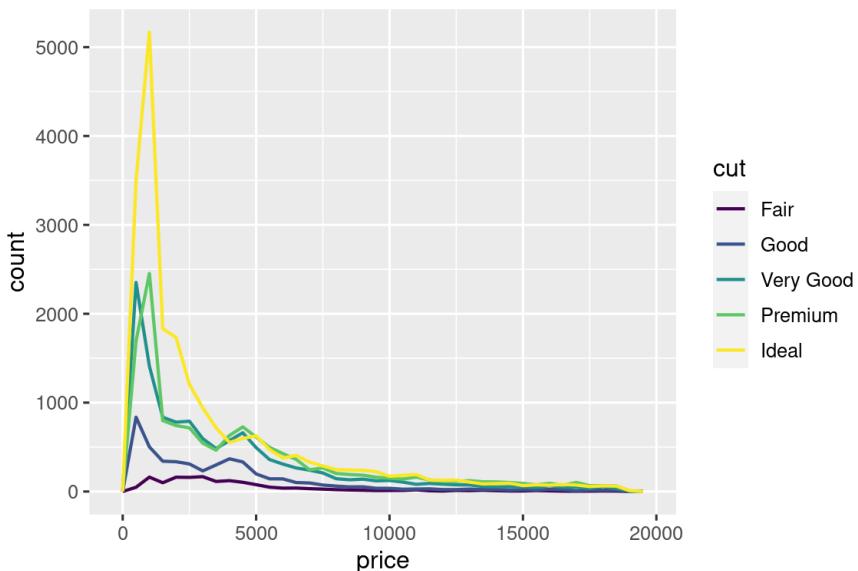

12.5 Covariation

If variation describes the behavior *within* a variable, covariation describes the behavior *between* variables. **Covariation** is the tendency for the values of two or more variables to vary together in a related way. The best way to spot covariation is to visualize the relationship between two or more variables.

12.5.1 A categorical and a numerical variable

For example, let's explore how the price of a diamond varies with its quality (measured by `cut`) using `geom_freqpoly()`:

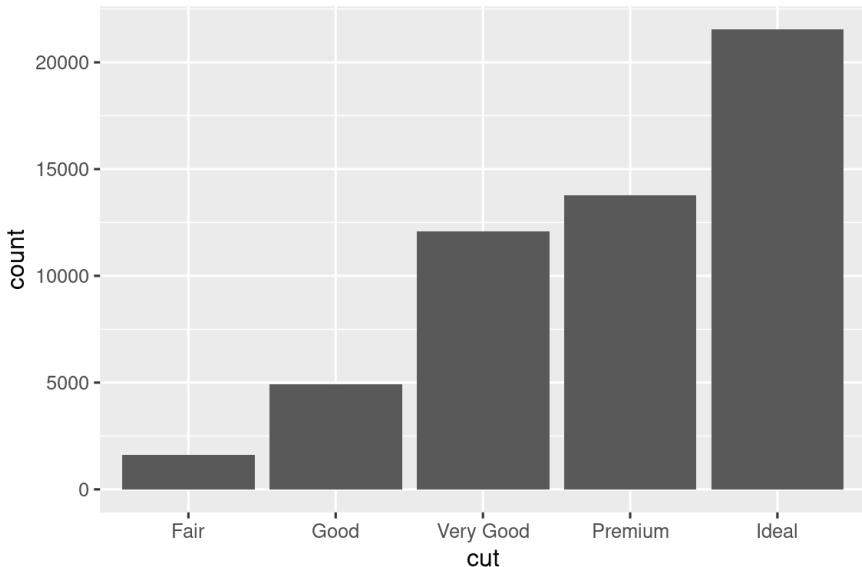

```
ggplot(diamonds, aes(x = price)) +  
  geom_freqpoly(aes(color = cut), binwidth = 500, size =  
#> Warning: Using `size` aesthetic for lines was depreca  
#> i Please use `linewidth` instead.
```

The default appearance of `geom_freqpoly()` is not that useful for that sort of comparison because the height is given by the count and the

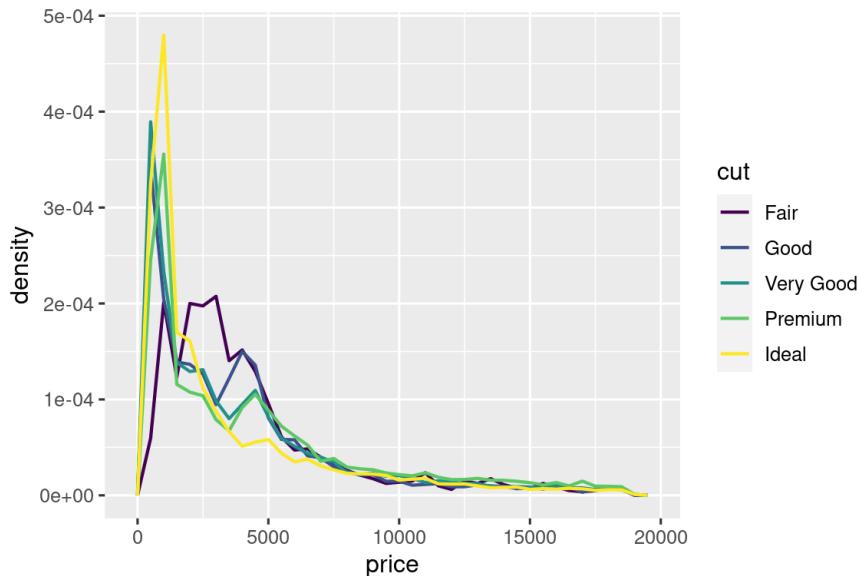

overall counts of `cut` in differ so much, making it hard to see the differences in the shapes of their distributions:

```
ggplot(diamonds, aes(x = cut)) +  
  geom_bar()
```

To make the comparison easier we need to swap what is displayed on the y-axis. Instead of displaying count, we'll display the **density**, which is the count standardized so that the area under each frequency polygon is one.

```
ggplot(diamonds, aes(x = price, y = after_stat(density))  
  geom_freqpoly(aes(color = cut), binwidth = 500, size =
```

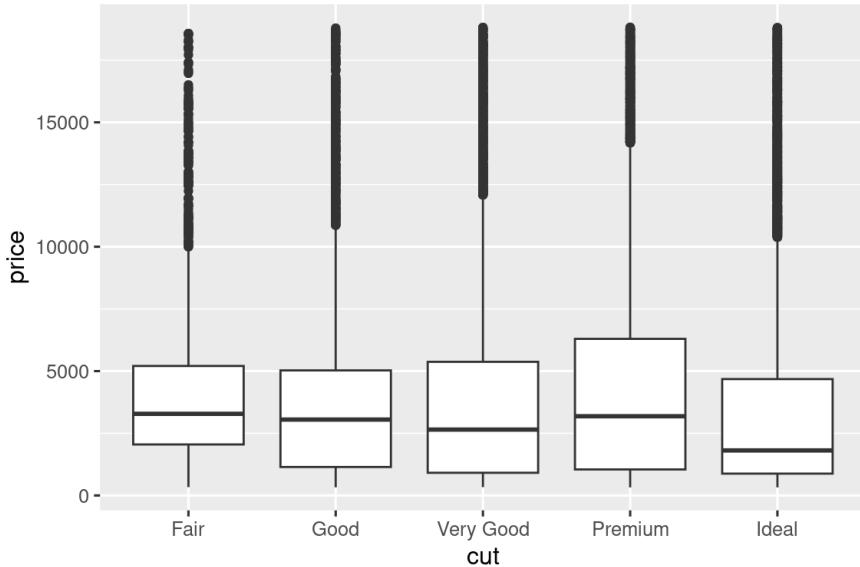

Note that we're mapping the density to the `y`, but since `density` is not a variable in the `diamonds` dataset, we need to first calculate it. We use the `after_stat()` function to do so.

There's something rather surprising about this plot - it appears that fair diamonds (the lowest quality) have the highest average price! But maybe that's because frequency polygons are a little hard to interpret - there's a lot going on in this plot.

A visually simpler plot for exploring this relationship is using side-by-side boxplots.

```
ggplot(diamonds, aes(x = cut, y = price)) +  
  geom_boxplot()
```

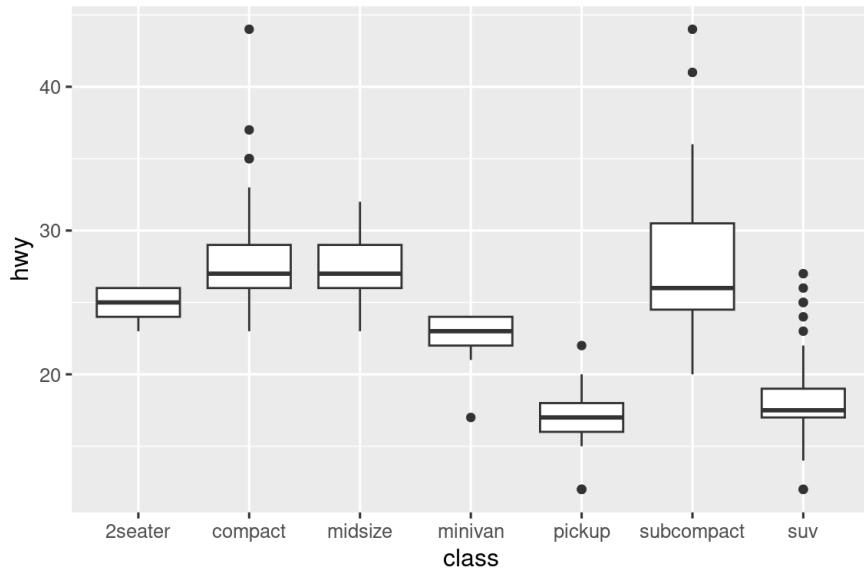

We see much less information about the distribution, but the boxplots are much more compact so we can more easily compare them (and fit more on one plot). It supports the counter-intuitive finding that better quality diamonds are cheaper on average! In the exercises, you'll be challenged to figure out why.

`cut` is an ordered factor: fair is worse than good, which is worse than very good and so on. Many categorical variables don't have such an intrinsic order, so you might want to reorder them to make a more informative display. One way to do that is with the `fct_reorder()` function.

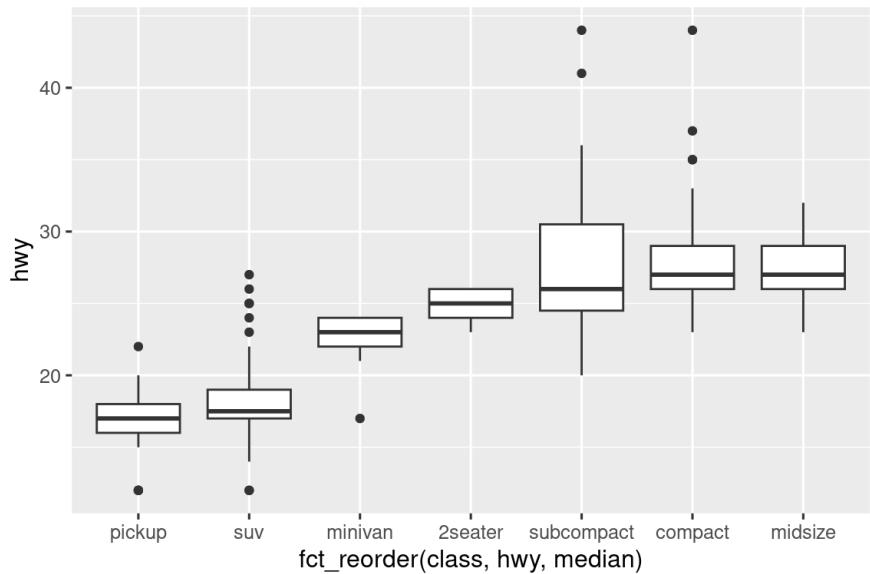

For example, take the `class` variable in the `mpg` dataset. You might be interested to know how highway mileage varies across classes:

```
ggplot(mpg, aes(x = class, y = hwy)) +  
  geom_boxplot()
```

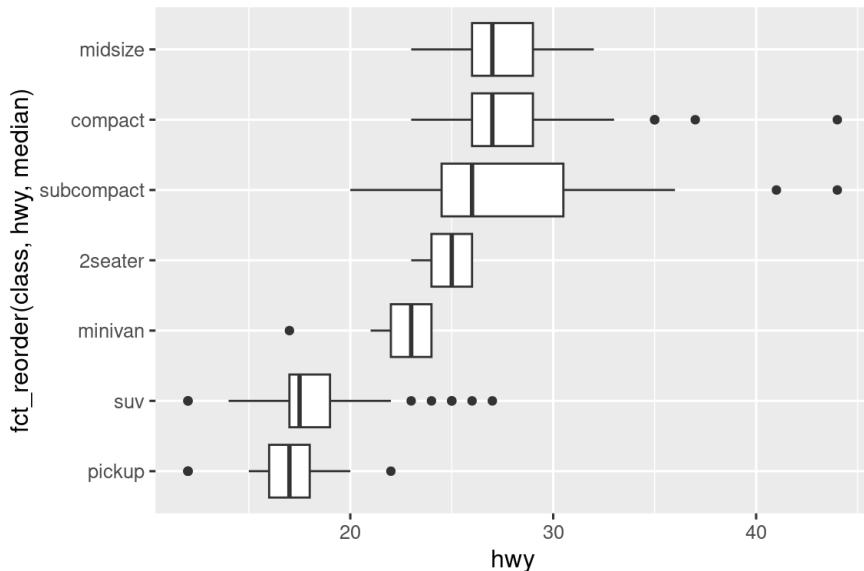

To make the trend easier to see, we can reorder `class` based on the median value of `hwy`:

```
ggplot(mpg,  
       aes(x = fct_reorder(class, hwy, median), y = hwy)  
       geom_boxplot())
```

If you have long variable names, `geom_boxplot()` will work better if you flip it 90°. You can do that by exchanging the x and y aesthetic mappings.

```
ggplot(mpg,  
       aes(x = hwy, y = fct_reorder(class, hwy, median))  
       geom_boxplot())
```

12.5.1.1 Exercises

1. Use what you've learned to improve the visualization of the departure times of cancelled vs. non-cancelled flights.
2. What variable in the diamonds dataset is most important for predicting the price of a diamond? How is that variable correlated with cut? Why does the combination of those two relationships lead to lower quality diamonds being more expensive?
3. Instead of exchanging the x and y variables, add `coord_flip()` as a new layer to the vertical boxplot to create a horizontal one. How does this compare to using exchanging the variables?
4. One problem with boxplots is that they were developed in an era of much smaller datasets and tend to display a prohibitively large number of “outlying values”. One approach to remedy this problem is the letter value plot. Install the lvplot package, and try using

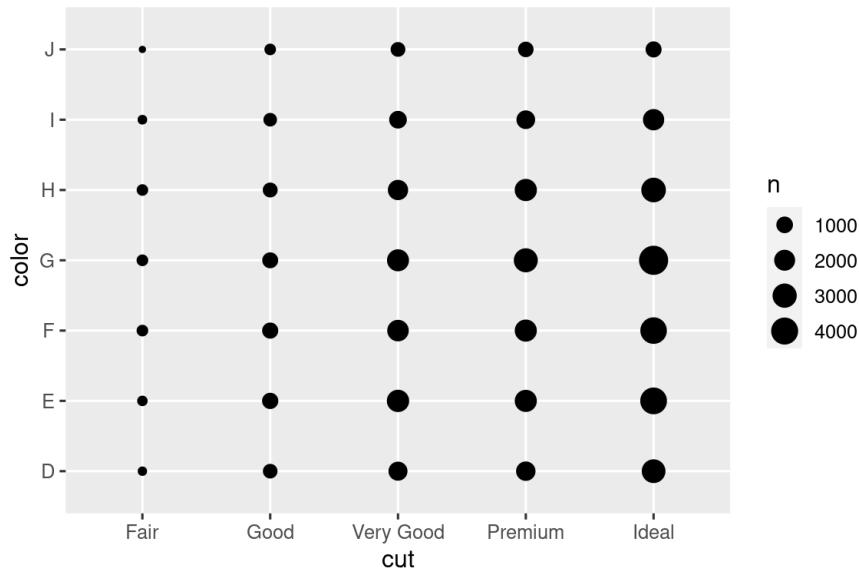

- `geom_lv()` to display the distribution of price vs. cut. What do you learn? How do you interpret the plots?
5. Compare and contrast `geom_violin()` with a faceted `geom_histogram()`, or a colored `geom_freqpoly()`. What are the pros and cons of each method?

6. If you have a small dataset, it's sometimes useful to use `geom_jitter()` to see the relationship between a continuous and categorical variable. The `ggbeeswarm` package provides a number of methods similar to `geom_jitter()`. List them and briefly describe what each one does.

12.5.2 Two categorical variables

To visualize the covariation between categorical variables, you'll need to count the number of observations for each combination of levels of these categorical variables. One way to do that is to rely on the built-in `geom_count()`:

```
ggplot(diamonds, aes(x = cut, y = color)) +  
  geom_count()
```

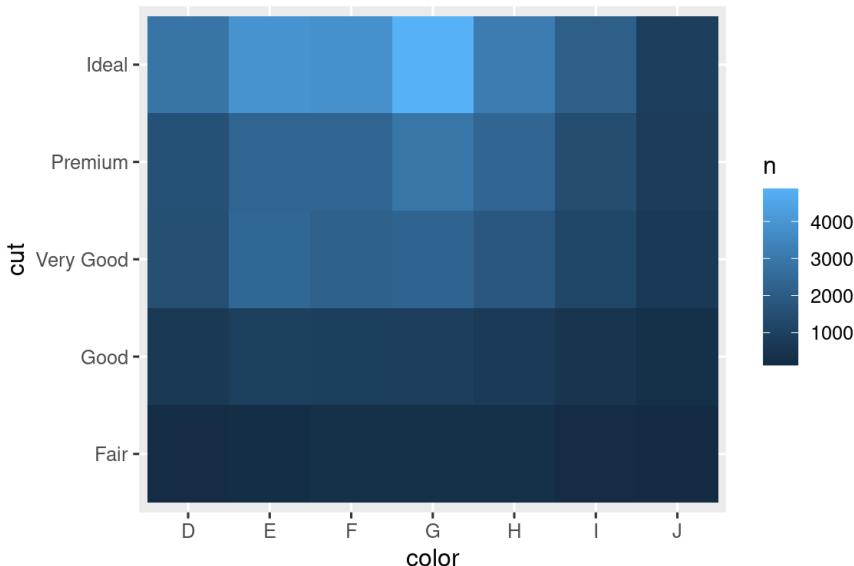

The size of each circle in the plot displays how many observations occurred at each combination of values. Covariation will appear as a strong correlation between specific x values and specific y values.

Another approach for exploring the relationship between these variables is computing the counts with dplyr:

```
diamonds |>
  count(color, cut)
#> # A tibble: 35 × 3
#>   color    cut       n
#>   <ord> <ord>     <int>
#> 1 D      Fair     163
#> 2 D      Good    662
#> 3 D      Very Good 1513
#> 4 D      Premium 1603
#> 5 D      Ideal    2834
#> 6 E      Fair     224
#> # ... with 29 more rows
```

Then visualize with `geom_tile()` and the `fill` aesthetic:

```
diamonds |>
  count(color, cut) |>
  ggplot(aes(x = color, y = cut)) +
  geom_tile(aes(fill = n))
```

If the categorical variables are unordered, you might want to use the `seriation` package to simultaneously reorder the rows and columns in order to more clearly reveal interesting patterns. For larger plots, you might want to try the `heatmaply` package, which creates interactive plots.

12.5.2.1 Exercises

1. How could you rescale the count dataset above to more clearly show the distribution of cut within color, or color within cut?
2. How does the segmented bar chart change if color is mapped to the `x` aesthetic and `cut` is mapped to the `fill` aesthetic? Calculate

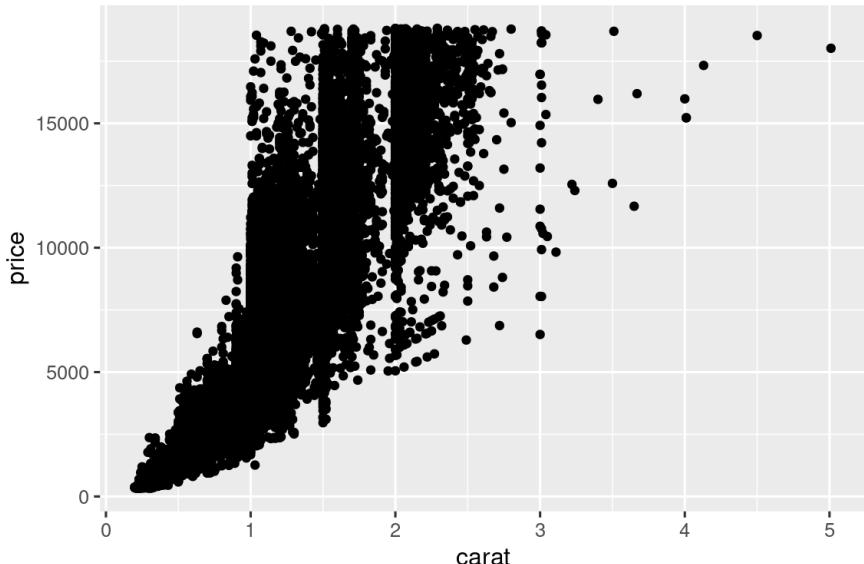

the counts that fall into each of the segments.

3. Use `geom_tile()` together with dplyr to explore how average flight delays vary by destination and month of year. What makes the plot difficult to read? How could you improve it?
4. Why is it slightly better to use `aes(x = color, y = cut)` rather than `aes(x = cut, y = color)` in the example above?

12.5.3 Two numerical variables

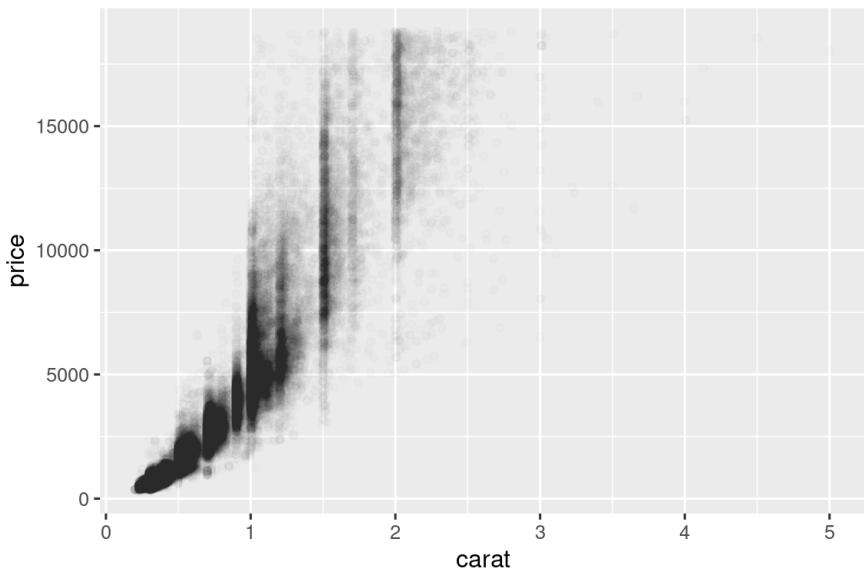

You've already seen one great way to visualize the covariation between two numerical variables: draw a scatterplot with `geom_point()`. You can see covariation as a pattern in the points. For example, you can see an exponential relationship between the carat size and price of a diamond.

```
ggplot(diamonds, aes(x = carat, y = price)) +  
  geom_point()
```

Scatterplots become less useful as the size of your dataset grows, because points begin to overplot, and pile up into areas of uniform black (as above). You've already seen one way to fix the problem: using the `alpha` aesthetic to add transparency.

```
ggplot(diamonds, aes(x = carat, y = price)) +  
  geom_point(alpha = 1 / 100)
```

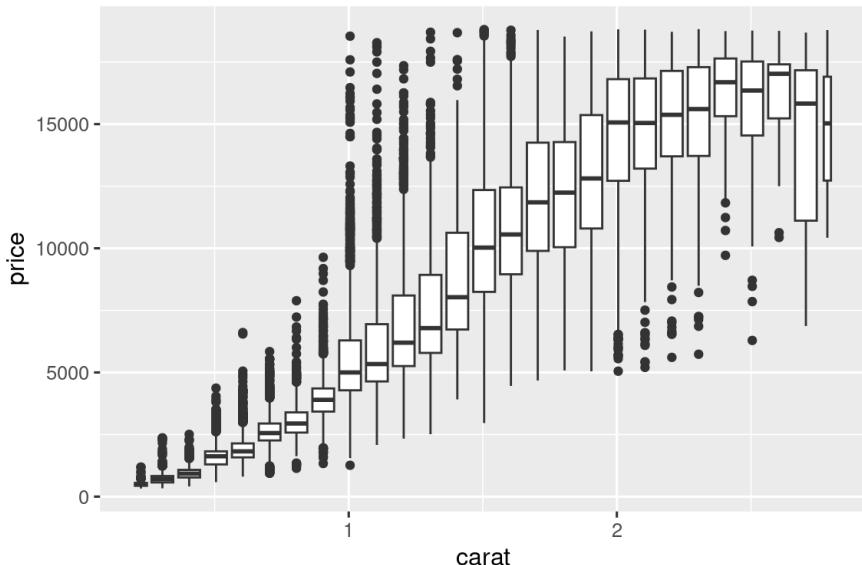

But using transparency can be challenging for very large datasets. Another solution is to use bin. Previously you used `geom_histogram()` and `geom_freqpoly()` to bin in one dimension. Now you'll learn how to use `geom_bin2d()` and `geom_hex()` to bin in two dimensions.

`geom_bin2d()` and `geom_hex()` divide the coordinate plane into 2d bins and then use a fill color to display how many points fall into each bin. `geom_bin2d()` creates rectangular bins. `geom_hex()` creates hexagonal bins. You will need to install the hexbin package to use `geom_hex()`.

```
ggplot(smaller, aes(x = carat, y = price)) +  
  geom_bin2d()  
  
# install.packages("hexbin")  
ggplot(smaller, aes(x = carat, y = price)) +  
  geom_hex()
```

Another option is to bin one continuous variable so it acts like a categorical variable. Then you can use one of the techniques for visualizing the combination of a categorical and a continuous variable that you learned about. For example, you could bin `carat` and then for each group, display a boxplot:

```
ggplot(smaller, aes(x = carat, y = price)) +  
  geom_boxplot(aes(group = cut_width(carat, 0.1)))
```

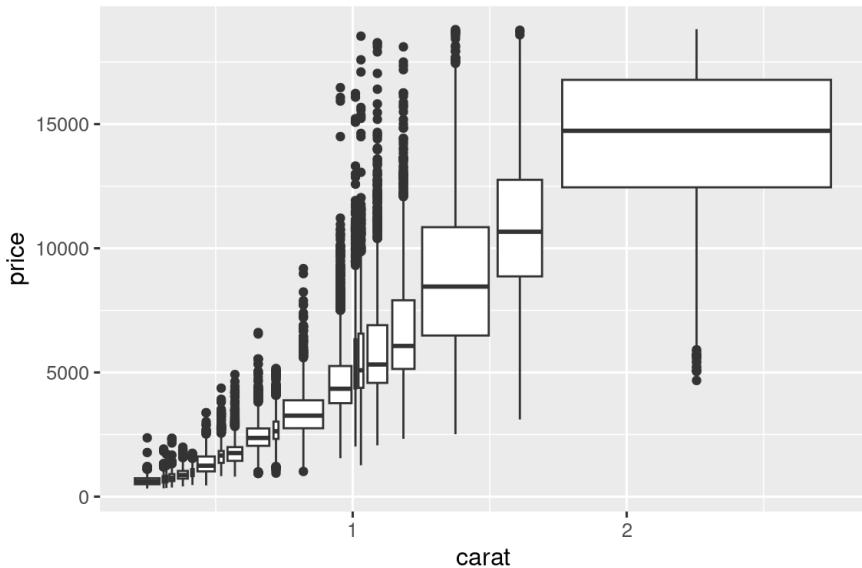

`cut_width(x, width)`, as used above, divides `x` into bins of width `width`. By default, boxplots look roughly the same (apart from number

of outliers) regardless of how many observations there are, so it's difficult to tell that each boxplot summarizes a different number of points. One way to show that is to make the width of the boxplot proportional to the number of points with `varwidth = TRUE`.

Another approach is to display approximately the same number of points in each bin. That's the job of `cut_number()`:

```
ggplot(smaller, aes(x = carat, y = price)) +  
  geom_boxplot(aes(group = cut_number(carat, 20)))
```

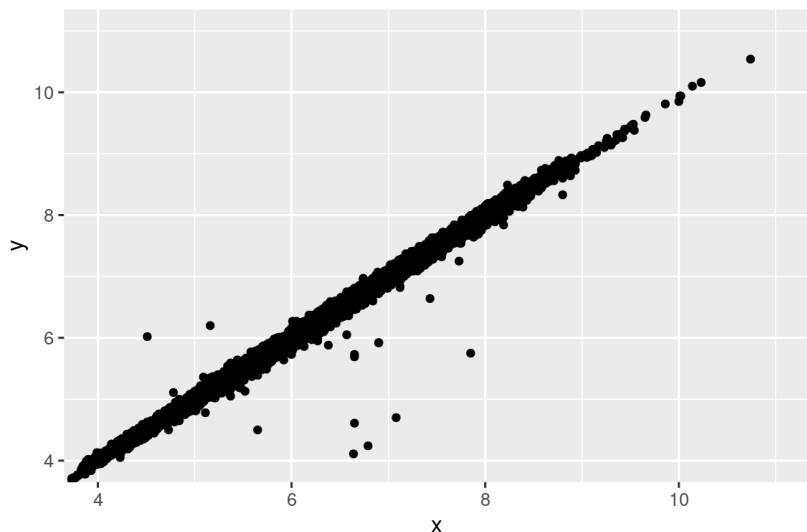

12.5.3.1 Exercises

1. Instead of summarizing the conditional distribution with a boxplot, you could use a frequency polygon. What do you need to consider when using `cut_width()` vs. `cut_number()`? How does that impact a visualization of the 2d distribution of `carat` and `price`?
2. Visualize the distribution of `carat`, partitioned by `price`.

- How does the price distribution of very large diamonds compare to small diamonds? Is it as you expect, or does it surprise you?
- Combine two of the techniques you've learned to visualize the combined distribution of cut, carat, and price.
- Two dimensional plots reveal outliers that are not visible in one dimensional plots. For example, some points in the plot below have an unusual combination of `x` and `y` values, which makes the points outliers even though their `x` and `y` values appear normal when examined separately.

```
ggplot(diamonds, aes(x = x, y = y)) +  
  geom_point() +  
  coord_cartesian(xlim = c(4, 11), ylim = c(4, 11))
```

Why is a scatterplot a better display than a binned plot for this case?

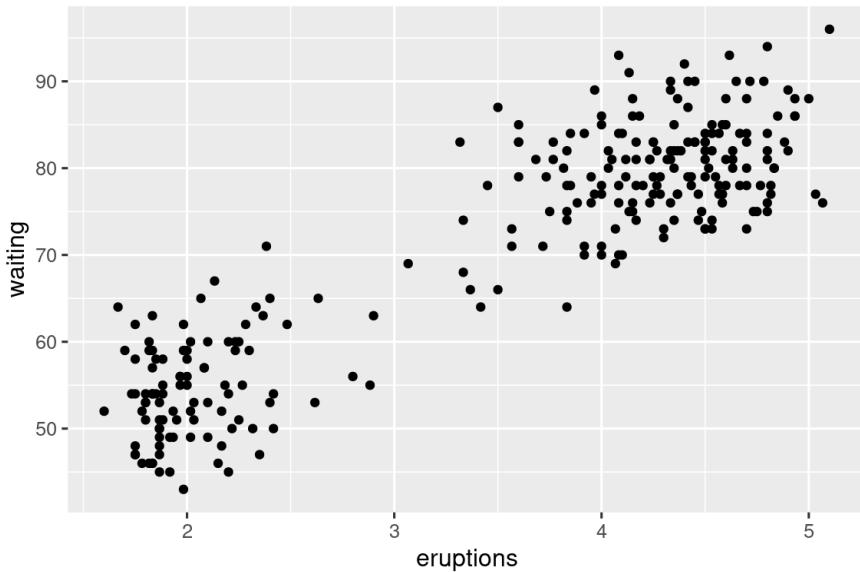

12.6 Patterns and models

Patterns in your data provide clues about relationships. If a systematic relationship exists between two variables it will appear as a pattern in the data. If you spot a pattern, ask yourself:

- Could this pattern be due to coincidence (i.e. random chance)?
- How can you describe the relationship implied by the pattern?
- How strong is the relationship implied by the pattern?
- What other variables might affect the relationship?
- Does the relationship change if you look at individual subgroups of the data?

A scatterplot of Old Faithful eruption lengths versus the wait time between eruptions shows a pattern: longer wait times are associated with longer eruptions. The scatterplot also displays the two clusters that we noticed above.

```
ggplot(faithful, aes(x = eruptions, y = waiting)) +  
  geom_point()
```

Patterns provide one of the most useful tools for data scientists because they reveal covariation. If you think of variation as a phenomenon that creates uncertainty, covariation is a phenomenon that reduces it. If two variables covary, you can use the values of one variable to make better predictions about the values of the second. If the covariation is due to a causal relationship (a special case), then you can use the value of one variable to control the value of the second.

Models are a tool for extracting patterns out of data. For example, consider the diamonds data. It's hard to understand the relationship between cut and price, because cut and carat, and carat and price are tightly related. It's possible to use a model to remove the very strong relationship between price and carat so we can explore the subtleties that remain. The following code fits a model that predicts `price` from `carat` and then computes the residuals (the difference between the predicted value and the actual value). The residuals give us a view of the price of the diamond, once the effect of carat has been removed. Note that instead of using the raw values of `price` and `carat`, we log

transform them first, and fit a model to the log-transformed values. Then, we exponentiate the residuals to put them back in the scale of raw prices.

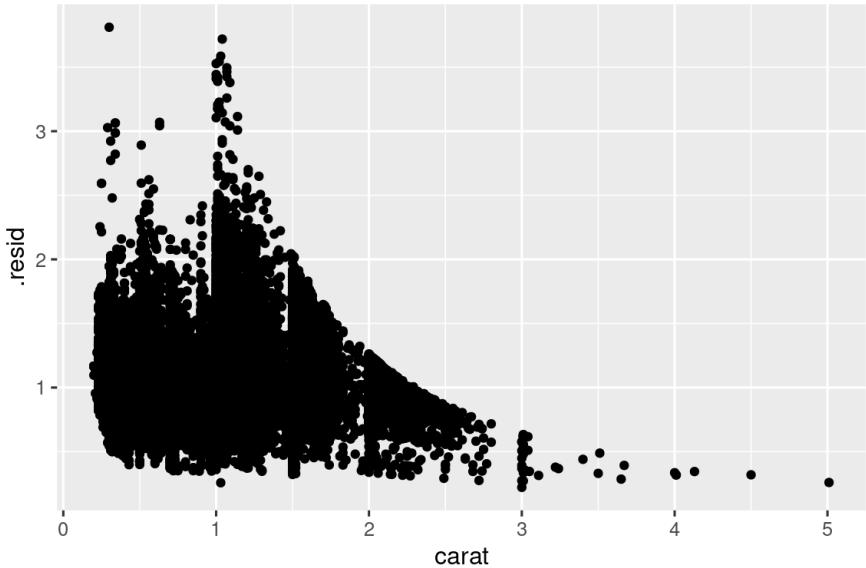

```
library(tidymodels)

diamonds <- diamonds |>
  mutate(
    log_price = log(price),
    log_carat = log(carat)
  )

diamonds_fit <- linear_reg() |>
  fit(log_price ~ log_carat, data = diamonds)

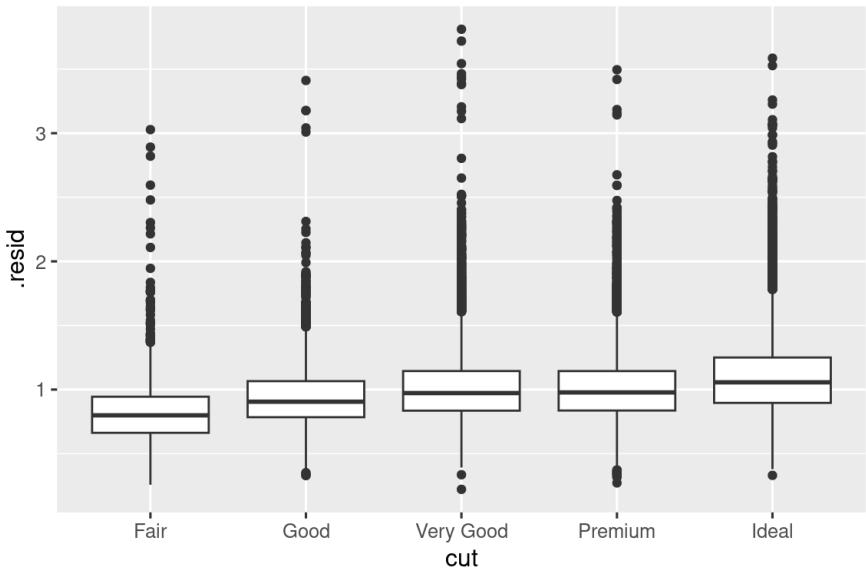

diamonds_aug <- augment(diamonds_fit, new_data = diamonds) |>
  mutate(.resid = exp(.resid))

ggplot(diamonds_aug, aes(x = carat, y = .resid)) +
  geom_point()
```

Once you've removed the strong relationship between carat and price, you can see what you expect in the relationship between cut and price: relative to their size, better quality diamonds are more expensive.

```
ggplot(diamonds_aug, aes(x = cut, y = .resid)) +  
  geom_boxplot()
```

We're not discussing modelling in this book because understanding what models are and how they work is easiest once you have tools of data wrangling and programming in hand.

12.7 Summary

In this chapter you've learned a variety of tools to help you understand the variation within your data. You've seen techniques that work with a single variable at a time and with a pair of variables. This might seem painful and restrictive if you have tens or hundreds of variables in your data, but they're the foundation upon which all other techniques are built.

In the next chapter, we'll tackle our final piece of workflow advice: how to get help when you're stuck.

1. Remember that when you need to be explicit about where a function (or dataset) comes from, we'll use the special form

`package::function()` or `package::dataset.` 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

13.1 Introduction

In [Chapter 12](#), you learned how to use plots as tools for *exploration*. When you make exploratory plots, you know—even before looking—which variables the plot will display. You made each plot for a purpose, could quickly look at it, and then move on to the next plot. In the course of most analyses, you’ll produce tens or hundreds of plots, most of which are immediately thrown away.

Now that you understand your data, you need to *communicate* your understanding to others. Your audience will likely not share your background knowledge and will not be deeply invested in the data. To help others quickly build up a good mental model of the data, you will need to invest considerable effort in making your plots as self-explanatory as possible. In this chapter, you’ll learn some of the tools that ggplot2 provides to do so.

This chapter focuses on the tools you need to create good graphics. We assume that you know what you want, and just need to know how to do it. For that reason, we highly recommend pairing this chapter with a good general visualization book. We particularly like [The Truthful Art](#), by Albert Cairo. It doesn’t teach the mechanics of creating visualizations,

but instead focuses on what you need to think about in order to create effective graphics.

13.1.1 Prerequisites

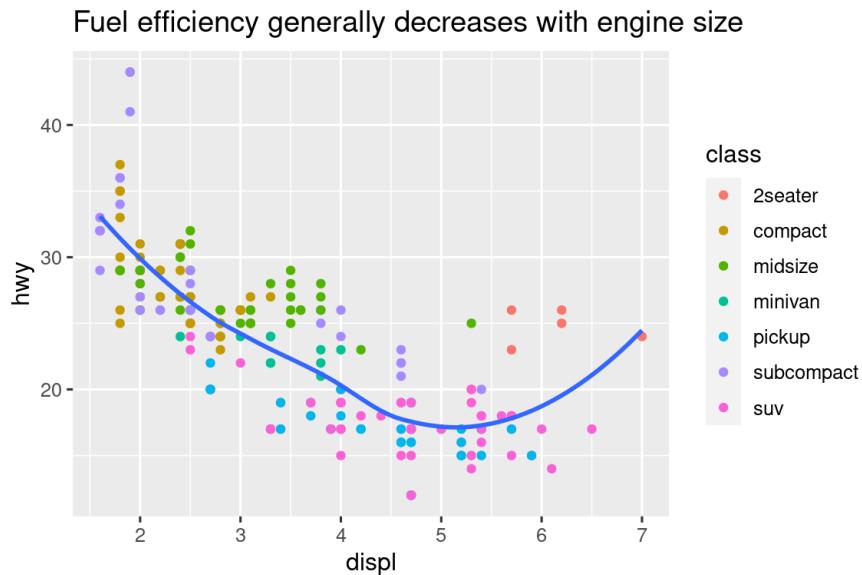

In this chapter, we'll focus once again on ggplot2. We'll also use a little dplyr for data manipulation, **scales** to override the default breaks, labels, transformations and palettes, and a few ggplot2 extension packages, including **ggrepel** (<https://ggrepel.slowkow.com>) by Kamil Slowikowski and **patchwork** (<https://patchwork.data-imaginist.com>) by Thomas Lin Pedersen. Don't forget that you'll need to install those packages with `install.packages()` if you don't already have them.

```
library(tidyverse)
#> — Attaching packages —
#> ✓ ggplot2 3.4.0           ✓ purrr   1.0.1.9000
#> ✓ tibble   3.1.8           ✓ dplyr    1.0.99.9000
#> ✓ tidyr    1.2.1.9001      ✓ stringr 1.5.0
#> ✓ readr    2.1.3           ✓ forcats 0.5.2
#> — Conflicts —
#> ✗ dplyr::filter() masks stats::filter()
#> ✗ dplyr::lag()   masks stats::lag()
library(ggrepel)
library(patchwork)
```

13.2 Labels

The easiest place to start when turning an exploratory graphic into an expository graphic is with good labels. You add labels with the `labs()` function. This example adds a plot title:

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class)) +  
  geom_smooth(se = FALSE) +  
  labs(title = "Fuel efficiency generally decreases with
```

The purpose of a plot title is to summarize the main finding. Avoid titles that just describe what the plot is, e.g. "A scatterplot of engine displacement vs. fuel economy".

If you need to add more text, there are two other useful labels:

- `subtitle` adds additional detail in a smaller font beneath the title.
- `caption` adds text at the bottom right of the plot, often used to describe the source of the data.

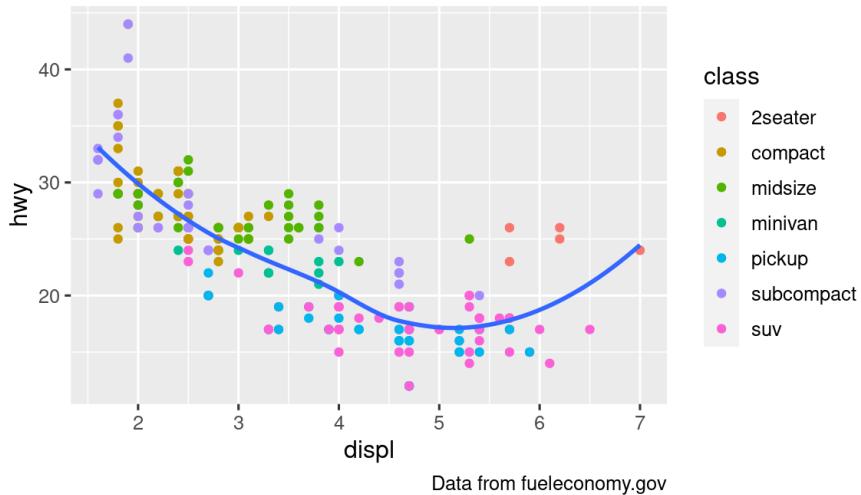

```

ggplot(mpg, aes(x = displ, y = hwy)) +
  geom_point(aes(color = class)) +
  geom_smooth(se = FALSE) +
  labs(
    title = "Fuel efficiency generally decreases with engine size",
    subtitle = "Two seaters (sports cars) are an exception because of their light weight",
    caption = "Data from fueleconomy.gov"
  )

```

Fuel efficiency generally decreases with engine size

Two seaters (sports cars) are an exception because of their light weight

Data from fueleconomy.gov

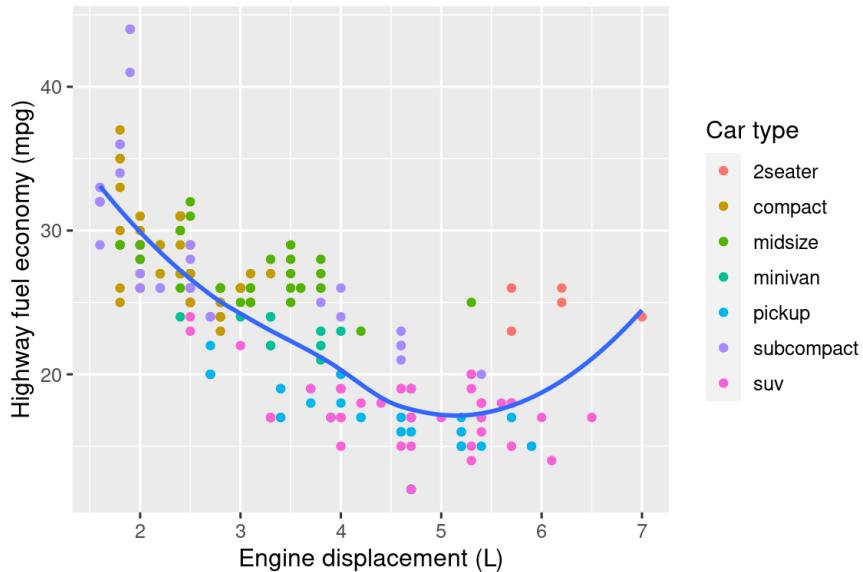

You can also use `labs()` to replace the axis and legend titles. It's usually a good idea to replace short variable names with more detailed descriptions, and to include the units.

```

ggplot(mpg, aes(x = displ, y = hwy)) +
  geom_point(aes(color = class)) +
  geom_smooth(se = FALSE) +
  labs(

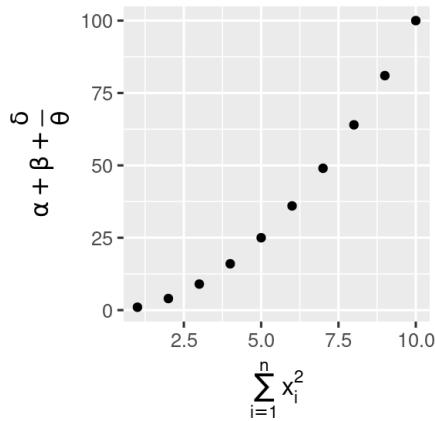

```

```
x = "Engine displacement (L)",  
y = "Highway fuel economy (mpg)",  
color = "Car type"  
)
```

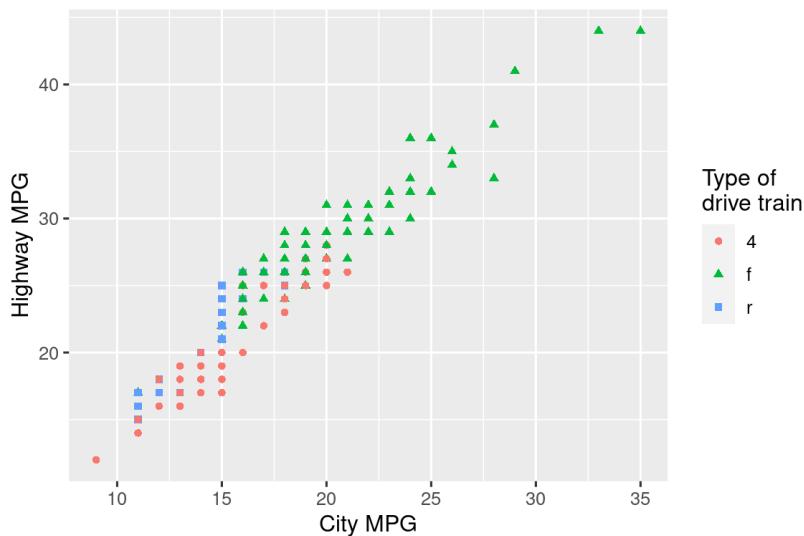

It's possible to use mathematical equations instead of text strings. Just switch `""` out for `quote()` and read about the available options in `?plotmath`:

```
df <- tibble(  
  x = 1:10,  
  y = x ^ 2  
)  
  
ggplot(df, aes(x, y)) +  
  geom_point() +  
  labs(  
    x = quote(sum(x[i] ^ 2, i == 1, n)),  
    y = quote(alpha + beta + frac(delta, theta)))  
)
```

13.2.1 Exercises

1. Create one plot on the fuel economy data with customized `title`, `subtitle`, `caption`, `x`, `y`, and `color` labels.
2. Recreate the following plot using the fuel economy data. Note that both the colors and shapes of points vary by type of drive train.

3. Take an exploratory graphic that you've created in the last month, and add informative titles to make it easier for others to understand.

13.3 Annotations

In addition to labelling major components of your plot, it's often useful to label individual observations or groups of observations. The first tool you have at your disposal is `geom_text()`. `geom_text()` is similar to `geom_point()`, but it has an additional aesthetic: `label`. This makes it possible to add textual labels to your plots.

There are two possible sources of labels. First, you might have a tibble that provides labels. In the following plot we pull out the cars with the highest engine size in each drive type and save their information as a new data frame called `label_info`. In order to create the `label_info` data frame we used a number of new dplyr functions. You'll learn more about each of these soon!

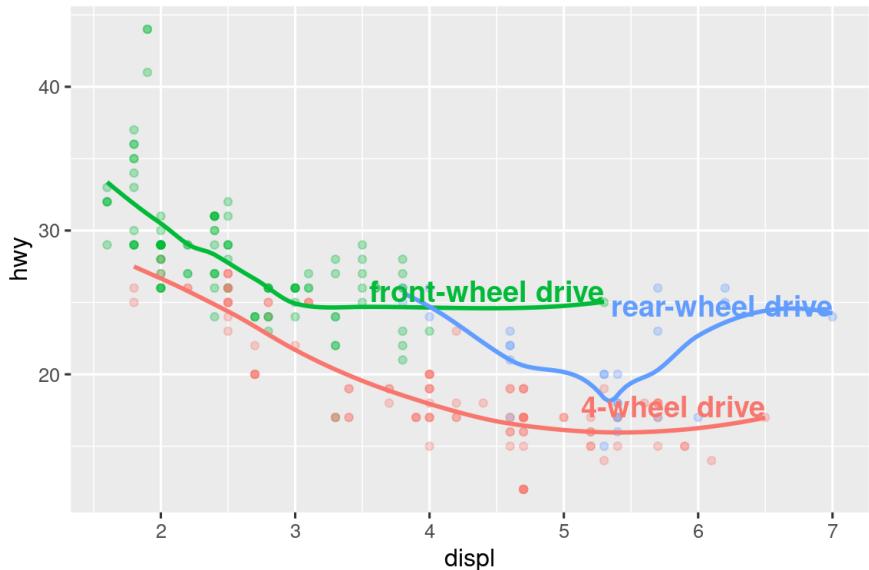

```
label_info <- mpg |>
  group_by(drv) |>
  arrange(desc(displ)) |>
  slice_head(n = 1) |>
  mutate(
    drive_type = case_when(
      drv == "f" ~ "front-wheel drive",
      drv == "r" ~ "rear-wheel drive",
      drv == "4" ~ "4-wheel drive"
    )
  ) |>
  select(displ, hwy, drv, drive_type)

label_info
#> # A tibble: 3 × 4
```

```
#> # Groups:   drv [3]
#>   displ   hwy  drv   drive_type
#>   <dbl> <int> <chr> <chr>
#> 1   6.5     17  f    4-wheel drive
#> 2   5.3     25  f    front-wheel drive
#> 3   7       24  r    rear-wheel drive
```

Then, we use this new data frame to directly label the three groups to replace the legend with labels placed directly on the plot. Using the `fontface` and `size` arguments we can customize the look of the text labels. They're larger than the rest of the text on the plot and bolded. (`theme(legend.position = "none")` turns the legend off — we'll talk about it more shortly.)

```
ggplot(mpg, aes(x = displ, y = hwy, color = drv)) +
  geom_point(alpha = 0.3) +
  geom_smooth(se = FALSE) +
  geom_text(
    data = label_info,
    aes(x = displ, y = hwy, label = drive_type),
    fontface = "bold", size = 5, hjust = "right", vjust
  ) +
  theme(legend.position = "none")
#> `geom_smooth()` using method = 'loess' and formula =
```

Note the use of `hjust` and `vjust` to control the alignment of the label. [Figure 13.1](#) shows all nine possible combinations.

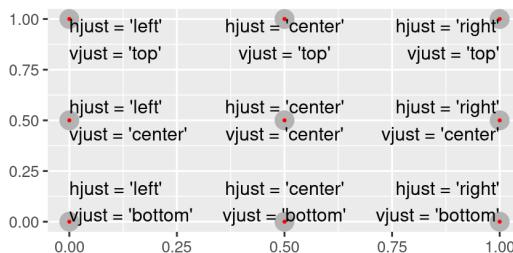

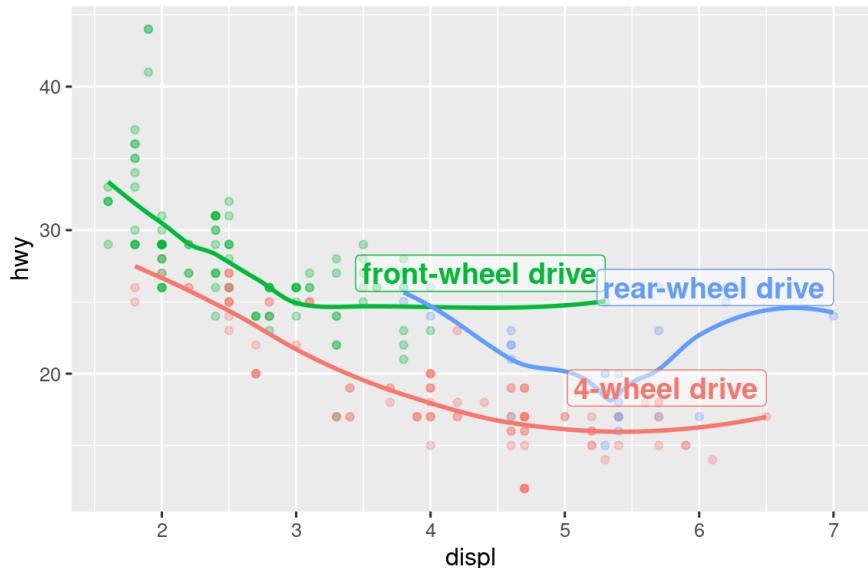

Figure 13.1: All nine combinations of `hjust` and `vjust`.

However the annotated plot we made above is hard to read because the labels overlap with each other, and with the points. We can make things a little better by switching to `geom_label()` which draws a rectangle behind the text. We also use the `nudge_y` parameter to move the labels slightly above the corresponding points:

```

ggplot(mpg, aes(x = displ, y = hwy, color = drv)) +
  geom_point(alpha = 0.3) +
  geom_smooth(se = FALSE) +
  geom_label(
    data = label_info,
    aes(x = displ, y = hwy, label = drive_type),
    fontface = "bold", size = 5, hjust = "right", alpha
  ) +
  theme(legend.position = "none")
#> `geom_smooth()` using method = 'loess' and formula =

```

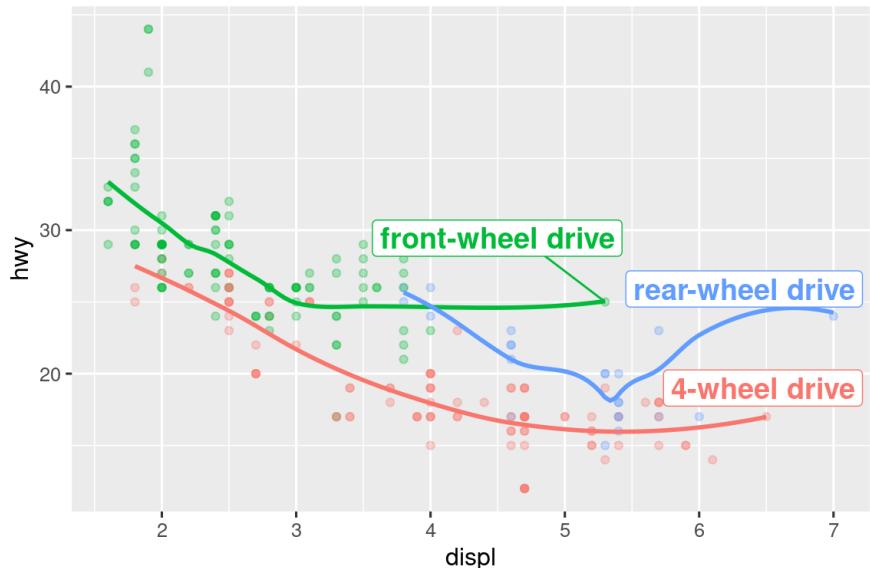

That helps a bit, but two of the labels still overlap with each other. This is difficult to fix by applying the same transformation for every label. Instead, we can use the `geom_label_repel()` function from the `ggrepel` package. This useful package will automatically adjust labels so that they don't overlap:

```

ggplot(mpg, aes(x = displ, y = hwy, color = drv)) +
  geom_point(alpha = 0.3) +
  geom_smooth(se = FALSE) +
  geom_label_repel(
    data = label_info,
    aes(x = displ, y = hwy, label = drive_type),
    fontface = "bold", size = 5, nudge_y = 2,
  ) +
  theme(legend.position = "none")
#> `geom_smooth()` using method = 'loess' and formula =

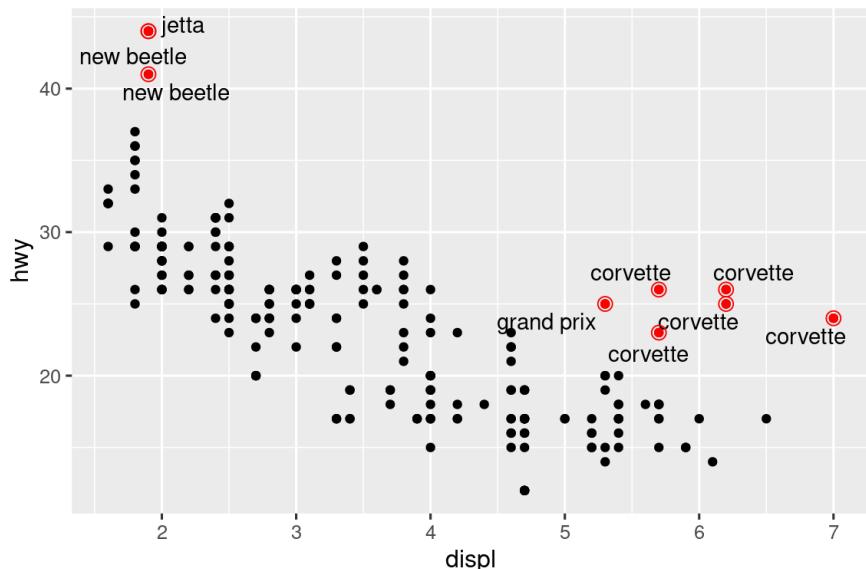

```

You can also use the same idea to highlight certain points on a plot with `geom_text_repel()` from the `ggrepel` package. Note another handy technique used here: we added a second layer of large, hollow points to further highlight the labelled points.

```
potential_outliers <- mpg |>
  filter(hwy > 40 | (hwy > 20 & displ > 5))

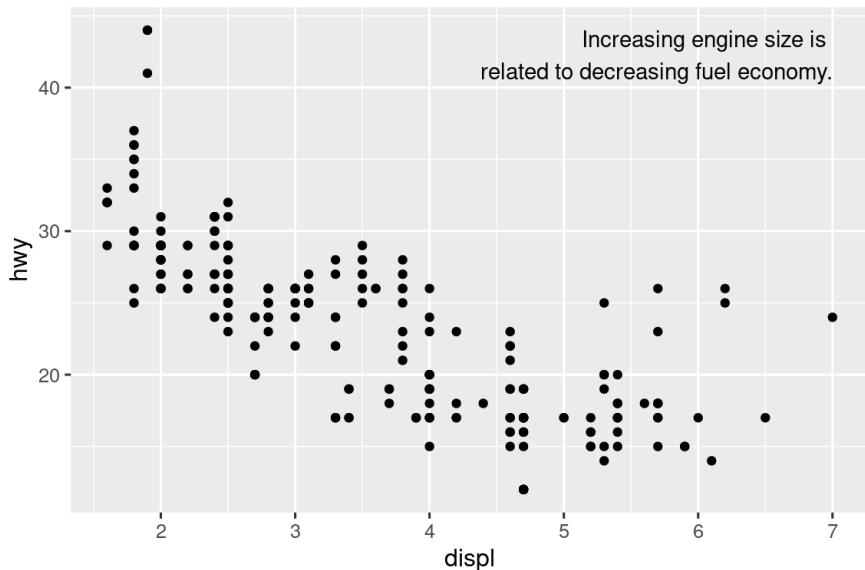

ggplot(mpg, aes(x = displ, y = hwy)) +
  geom_point() +
  geom_text_repel(data = potential_outliers, aes(label =
  geom_point(data = potential_outliers, color = "red") +
  geom_point(data = potential_outliers, color = "red", s
```

Alternatively, you might just want to add a single label to the plot, but you'll still need to create a data frame. Often, you want the label in the corner of the plot, so it's convenient to create a new data frame using `summarize()` to compute the maximum values of x and y.

```
label_info <- mpg |>
  summarize(
    displ = max(displ),
```

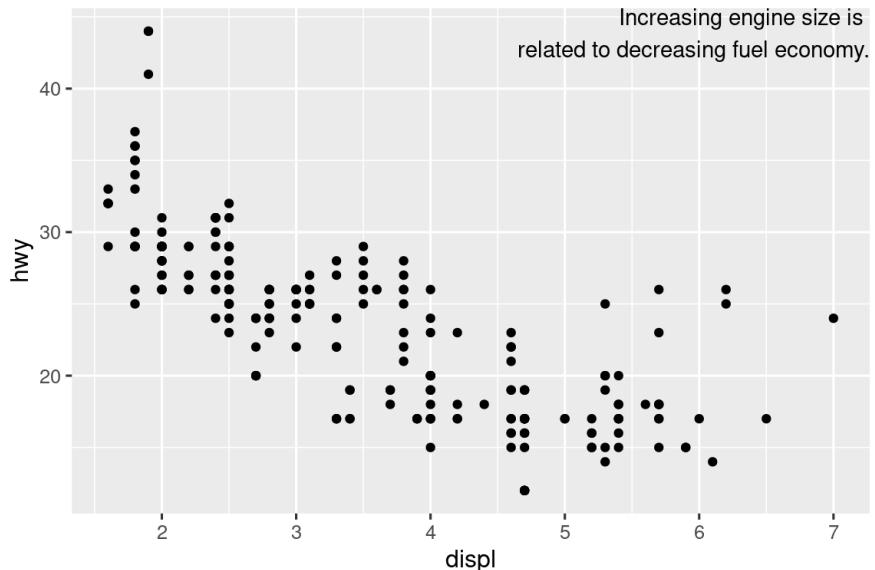

```
hwy = max(hwy),  
label = "Increasing engine size is \\nrelated to decr  
)  
  
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  geom_text(  
    data = label_info, aes(label = label),  
    vjust = "top", hjust = "right"  
)
```

If you want to place the text exactly on the borders of the plot, you can use `+Inf` and `-Inf`. Since we're no longer computing the positions from `mpg`, we can use `tibble()` to create the data frame:

```
label_info <- tibble(  
  displ = Inf,  
  hwy = Inf,
```

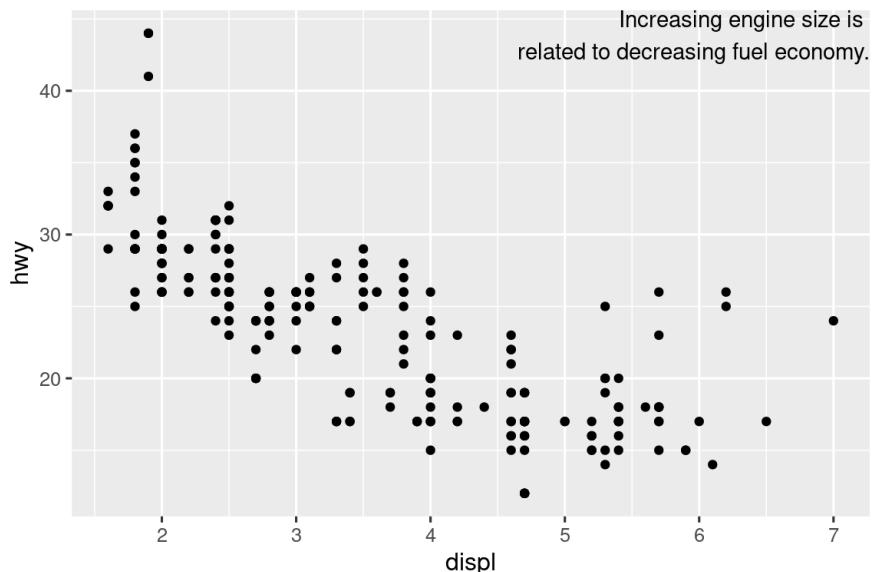

```
label = "Increasing engine size is \nrelated to decre  
)  
  
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  geom_text(data = label_info, aes(label = label), vjust
```

Alternatively, we can add the annotation without creating a new data frame, using `annotate()`. This function adds a geom to a plot, but it doesn't map variables of a data frame to an aesthetic. The first argument of this function, `geom`, is the geometric object you want to use for annotation.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  annotate(  
    geom = "text", x = Inf, y = Inf,  
    label = "Increasing engine size is \nrelated to decr
```

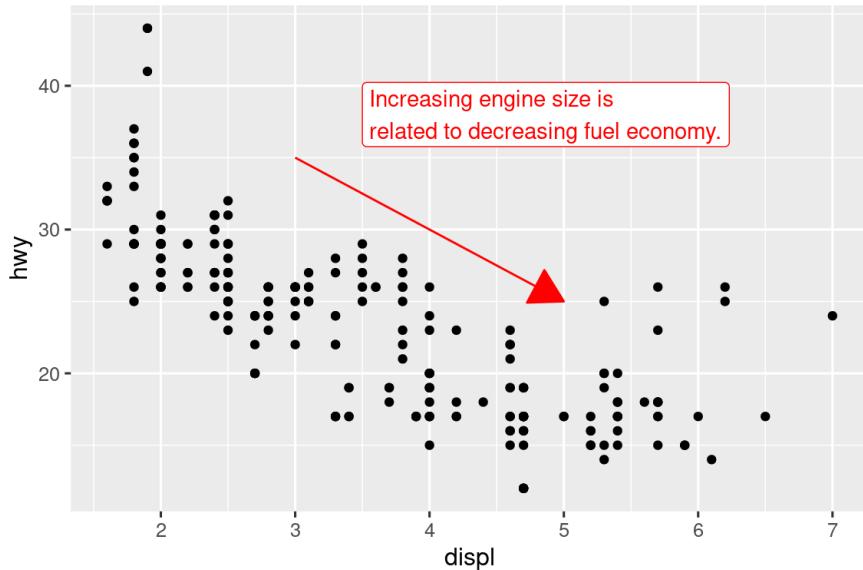

```
vjust = "top", hjust = "right"  
)
```

You can also use a `label` geom instead of a `text` geom like we did earlier, set aesthetics like color. Another approach for drawing attention to a plot feature is using a `segment` geom with the `arrow` argument. The `x` and `y` aesthetics define the starting location of the segment and `xend` and `yend` to define the end location.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  annotate(  
    geom = "label", x = 3.5, y = 38,  
    label = "Increasing engine size is \nrelated to decr  
    hjust = "left", color = "red"  
  ) +  
  annotate(  
    geom = "segment",
```

```
x = 3, y = 35, xend = 5, yend = 25, color = "red",
arrow = arrow(type = "closed")
)
```

In these examples, we manually broke the label up into lines using "`\n`". Another approach is to use `stringr::str_wrap()` to automatically add line breaks, given the number of characters you want per line:

```
"Increasing engine size is related to decreasing fuel ec
  str_wrap(width = 40) |>
  writeLines()
#> Increasing engine size is related to
#> decreasing fuel economy.
```

Remember, in addition to `geom_text()`, you have many other geoms in ggplot2 available to help annotate your plot. A couple ideas:

- Use `geom_hline()` and `geom_vline()` to add reference lines. We often make them thick (`size = 2`) and white (`color = white`), and draw them underneath the primary data layer. That makes them easy to see, without drawing attention away from the data.
- Use `geom_rect()` to draw a rectangle around points of interest. The boundaries of the rectangle are defined by aesthetics `xmin`, `xmax`, `ymin`, `ymax`.
- Use `geom_segment()` with the `arrow` argument to draw attention to a point with an arrow. Use aesthetics `x` and `y` to define the starting location, and `xend` and `yend` to define the end location.

The only limit is your imagination (and your patience with positioning annotations to be aesthetically pleasing)!

13.3.1 Exercises

1. Use `geom_text()` with infinite positions to place text at the four corners of the plot.
2. Use `annotate()` to add a point geom in the middle of your last plot without having to create a tibble. Customize the shape, size, or color of the point.
3. How do labels with `geom_text()` interact with faceting? How can you add a label to a single facet? How can you put a different label in each facet? (Hint: Think about the underlying data.)
4. What arguments to `geom_label()` control the appearance of the background box?

5. What are the four arguments to `arrow()`? How do they work?

Create a series of plots that demonstrate the most important options.

13.4 Scales

The third way you can make your plot better for communication is to adjust the scales. Scales control the mapping from data values to things that you can perceive.

13.4.1 Default scales

Normally, ggplot2 automatically adds scales for you. For example, when you type:

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class))
```

ggplot2 automatically adds default scales behind the scenes:

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class)) +  
  scale_x_continuous() +  
  scale_y_continuous() +  
  scale_color_discrete()
```

Note the naming scheme for scales: `scale_` followed by the name of the aesthetic, then `_`, then the name of the scale. The default scales are named according to the type of variable they align with: continuous, discrete, datetime, or date. There are lots of non-default scales which you'll learn about below.

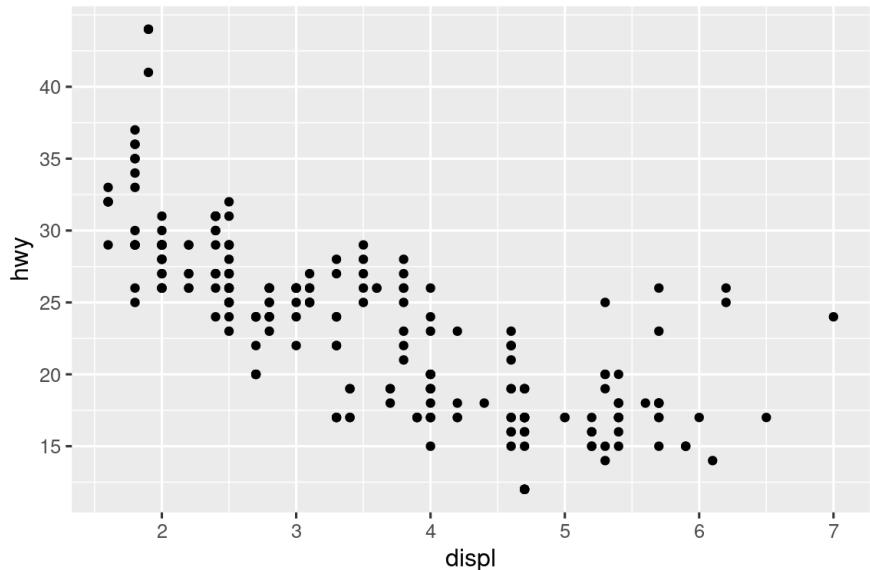

The default scales have been carefully chosen to do a good job for a wide range of inputs. Nevertheless, you might want to override the defaults for two reasons:

- You might want to tweak some of the parameters of the default scale. This allows you to do things like change the breaks on the axes, or the key labels on the legend.
- You might want to replace the scale altogether, and use a completely different algorithm. Often you can do better than the default because you know more about the data.

13.4.2 Axis ticks and legend keys

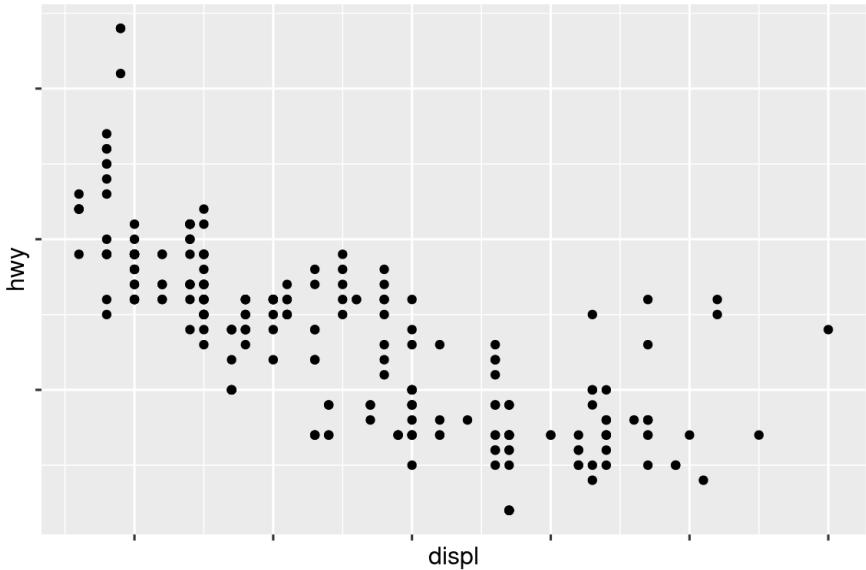

There are two primary arguments that affect the appearance of the ticks on the axes and the keys on the legend: `breaks` and `labels`. `Breaks` controls the position of the ticks, or the values associated with the keys. `Labels` controls the text label associated with each tick/key. The most common use of `breaks` is to override the default choice:

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  scale_y_continuous(breaks = seq(15, 40, by = 5))
```

You can use `labels` in the same way (a character vector the same length as `breaks`), but you can also set it to `NULL` to suppress the labels altogether. This is useful for maps, or for publishing plots where you can't share the absolute numbers.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  scale_x_continuous(labels = NULL) +  
  scale_y_continuous(labels = NULL)
```

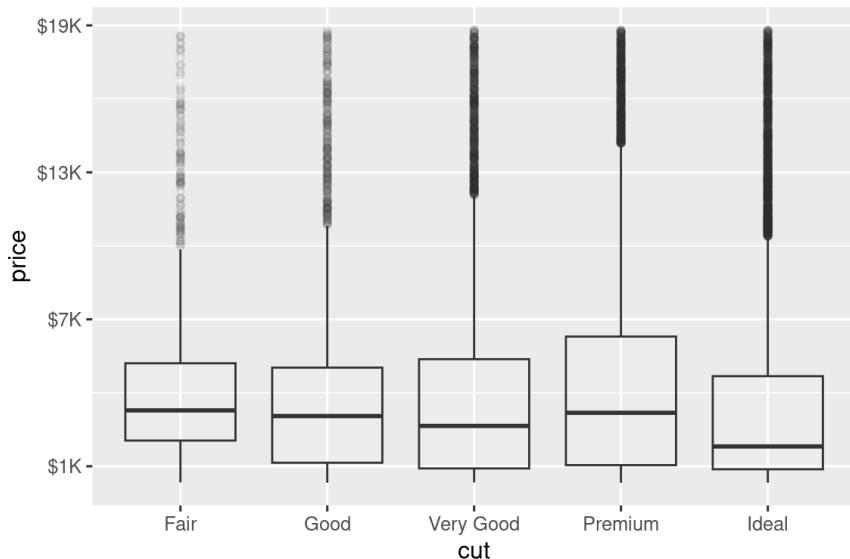

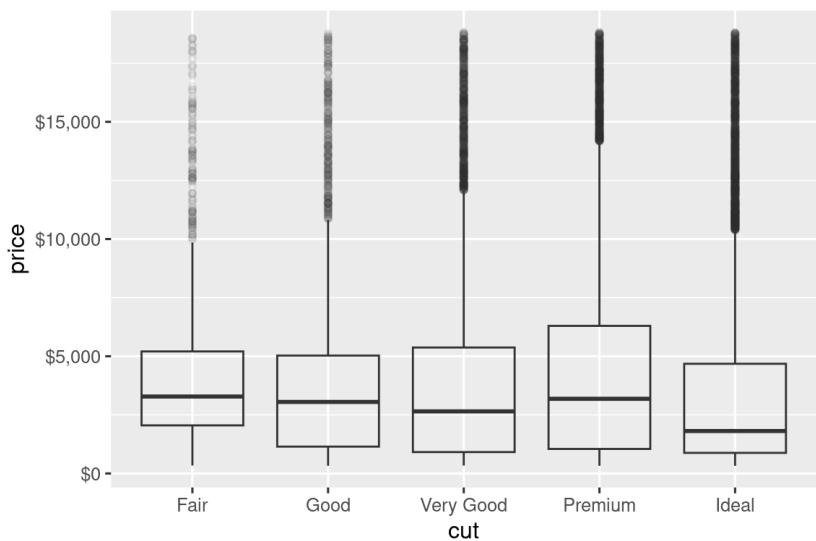

The `labels` argument coupled with labelling functions from the `scales` package is also useful for formatting numbers as currency, percent, etc. The plot on the left shows default labelling with `label_dollar()`, which adds a dollar sign as well as a thousand separator comma. The plot on the right adds further customization by dividing dollar values by 1,000 and adding a suffix “K” (for “thousands”) as well as adding custom breaks. Note that `breaks` is in the original scale of the data.

```
# Left
ggplot(diamonds, aes(x = cut, y = price)) +
  geom_boxplot(alpha = 0.05) +
  scale_y_continuous(labels = scales::label_dollar())

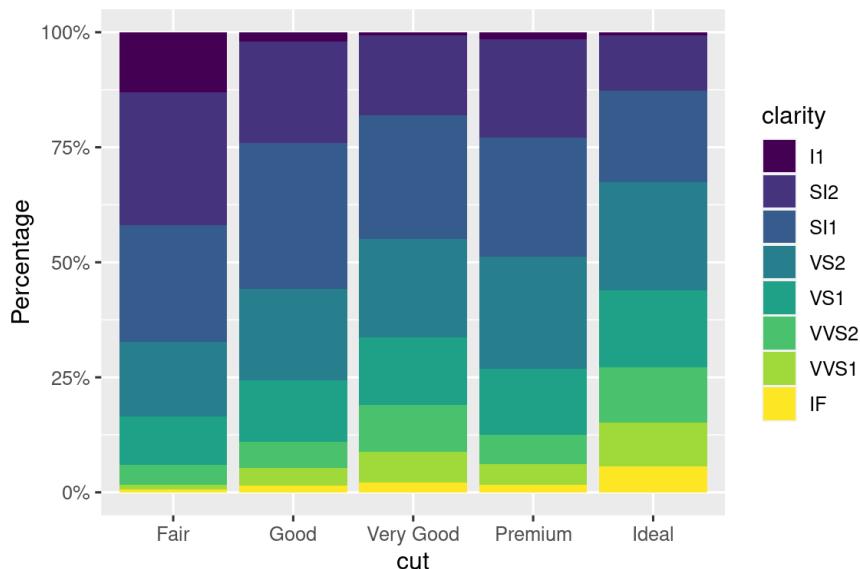

# Right
ggplot(diamonds, aes(x = cut, y = price)) +
  geom_boxplot(alpha = 0.05) +
  scale_y_continuous(
    labels = scales::label_dollar(scale = 1/1000, suffix = "K"))
```

```
breaks = seq(1000, 19000, by = 6000)
)
```

Another handy label function is `label_percent()`:

```
ggplot(diamonds, aes(x = cut, fill = clarity)) +
  geom_bar(position = "fill") +
  scale_y_continuous(
    name = "Percentage",
    labels = scales::label_percent()
)
```

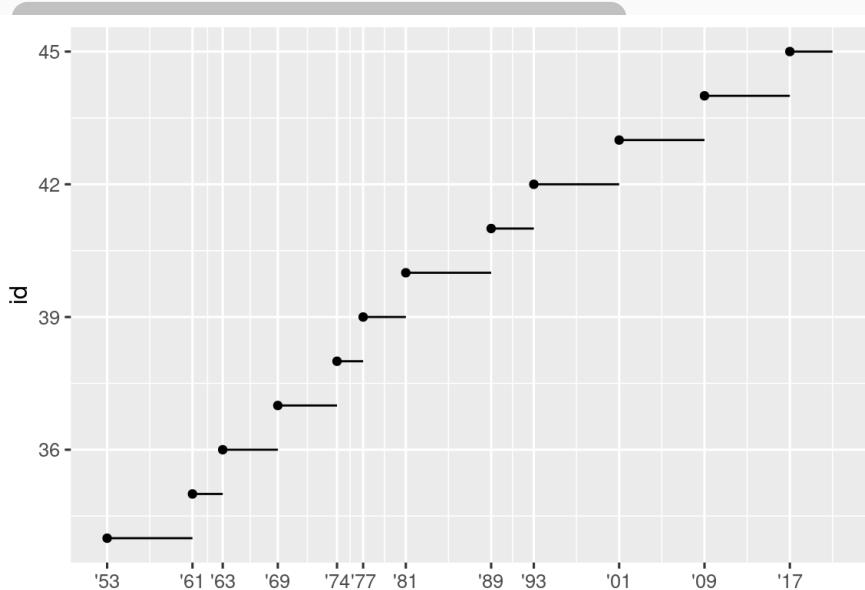

You can also use `breaks` and `labels` to control the appearance of legends. Collectively axes and legends are called **guides**. Axes are used for x and y aesthetics; legends are used for everything else.

Another use of `breaks` is when you have relatively few data points and want to highlight exactly where the observations occur. For example, take this plot that shows when each US president started and ended their term.

```
presidential |>
  mutate(id = 33 + row_number()) |>
  ggplot(aes(x = start, y = id)) +
```

```
geom_point() +  
  geom_segment(aes(xend = end, yend = id)) +  
  scale_x_date(name = NULL, breaks = presidential$start,
```

Note that the specification of breaks and labels for date and datetime scales is a little different:

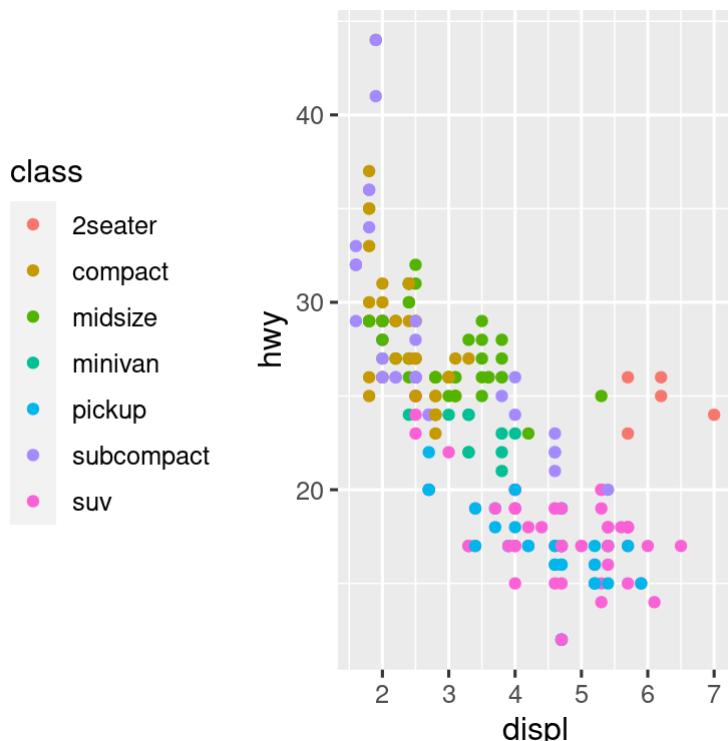

- `date_labels` takes a format specification, in the same form as `parse_datetime()`.
- `date_breaks` (not shown here), takes a string like “2 days” or “1 month”.

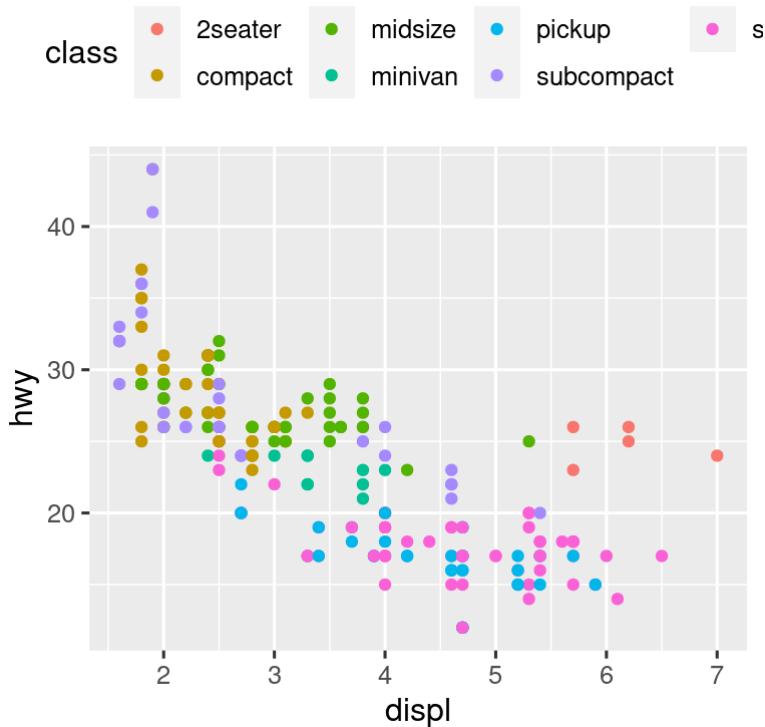

13.4.3 Legend layout

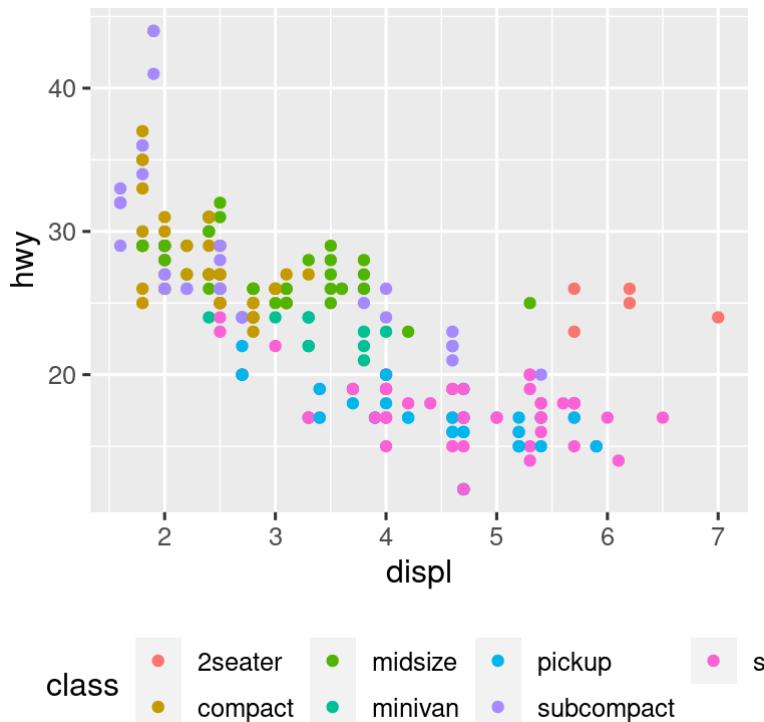

You will most often use `breaks` and `labels` to tweak the axes. While they both also work for legends, there are a few other techniques you are more likely to use.

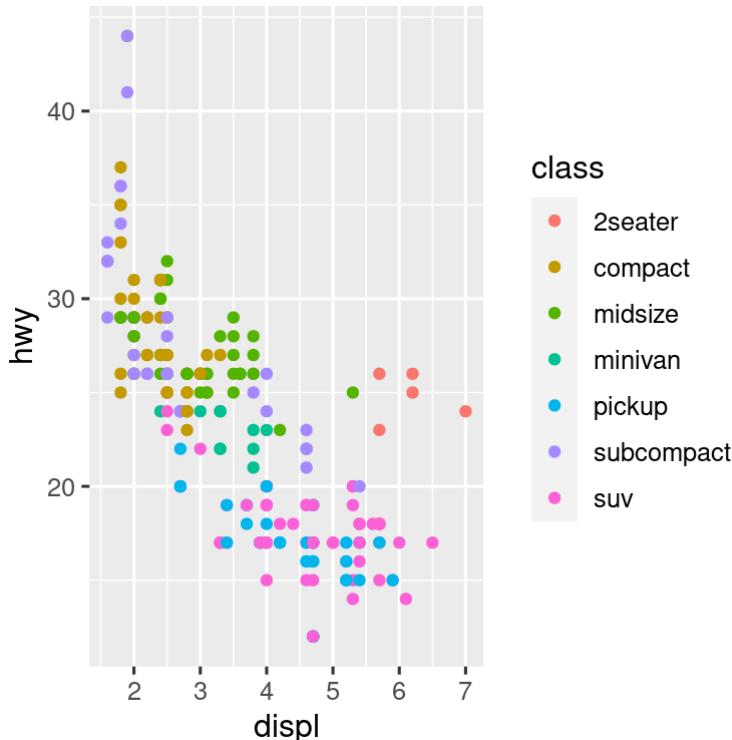

To control the overall position of the legend, you need to use a `theme()` setting. We'll come back to themes at the end of the chapter, but in brief, they control the non-data parts of the plot. The theme setting `legend.position` controls where the legend is drawn:

```
base <- ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class))  
  
base + theme(legend.position = "left")  
base + theme(legend.position = "top")  
base + theme(legend.position = "bottom")  
base + theme(legend.position = "right") # the default
```

You can also use `legend.position = "none"` to suppress the display of the legend altogether.

To control the display of individual legends, use `guides()` along with `guide_legend()` or `guide_colorbar()`. The following example shows two important settings: controlling the number of rows the legend uses with `nrow`, and overriding one of the aesthetics to make the points bigger. This is particularly useful if you have used a low `alpha` to display many points on a plot.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class)) +  
  geom_smooth(se = FALSE) +  
  theme(legend.position = "bottom") +
```

```
guides(color = guide_legend(nrow = 1, override.aes = 1  
#> `geom_smooth()` using method = 'loess' and formula =
```

Scatterplot of highway fuel efficiency versus engine size of cars where points are colored based on class of car. Overlaid on the plot is a smooth curve. The legend is in the bottom and classes are listed horizontally in a row. The points in the legend are larger than the points in the plot.

13.4.4 Replacing a scale

Instead of just tweaking the details a little, you can instead replace the scale altogether. There are two types of scales you're mostly likely to want to switch out: continuous position scales and color scales.

Fortunately, the same principles apply to all the other aesthetics, so once you've mastered position and color, you'll be able to quickly pick up other scale replacements.

It's very useful to plot transformations of your variable. For example, it's easier to see the precise relationship between `carat` and `price` if we log transform them:

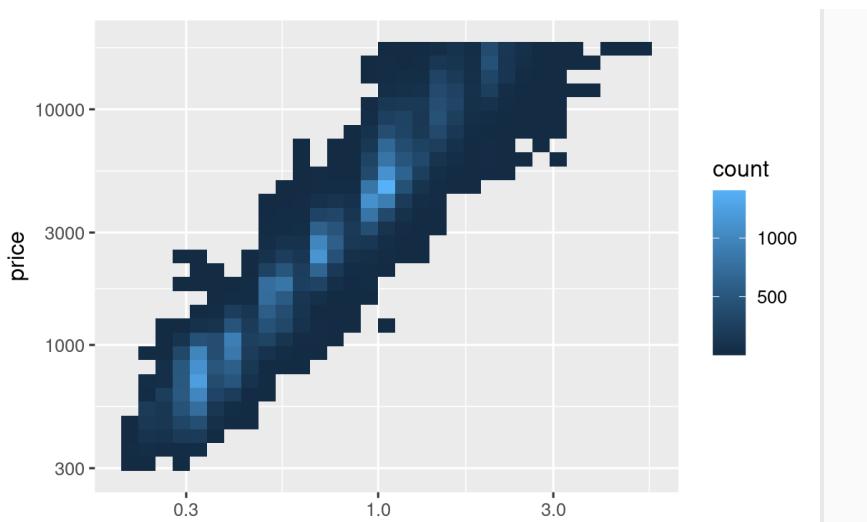

```
# Left  
ggplot(diamonds, aes(x = carat, y = price)) +  
  geom_bin2d()  
  
# Right  
ggplot(diamonds, aes(x = log10(carat), y = log10(price))  
  geom_bin2d()
```

 Two plots of price versus carat of diamonds. Data binned and the color of the rectangles representing each bin based on the number of points that fall into that bin. In the plot on the right, price and carat values are logged and the axis labels shows the logged values.

 Two plots of price versus carat of diamonds. Data binned and the color of the rectangles representing each bin based on the number of points that fall into that bin. In the plot on the right, price and carat values are logged and the axis labels shows the logged values.

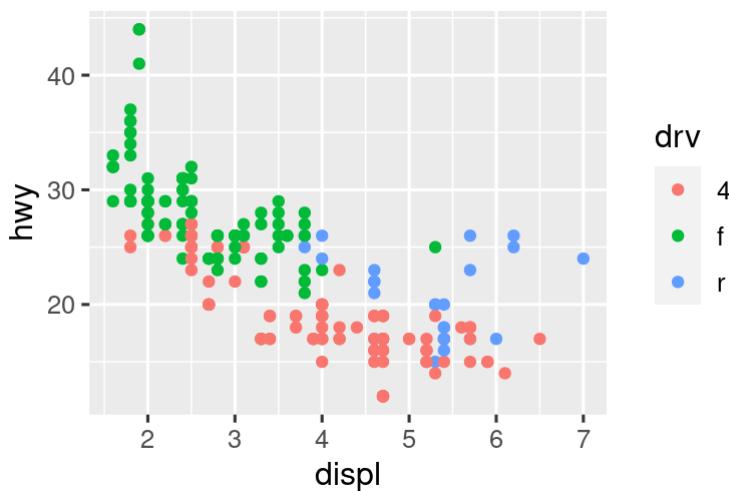

However, the disadvantage of this transformation is that the axes are now labelled with the transformed values, making it hard to interpret the plot. Instead of doing the transformation in the aesthetic mapping, we can instead do it with the scale. This is visually identical, except the axes are labelled on the original data scale.

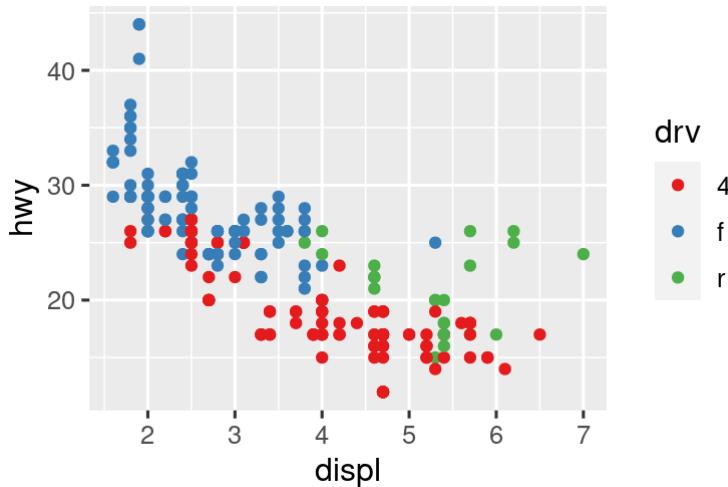

```
ggplot(diamonds, aes(x = carat, y = price)) +  
  geom_bin2d() +  
  scale_x_log10() +  
  scale_y_log10()
```

Another scale that is frequently customized is color. The default categorical scale picks colors that are evenly spaced around the color wheel. Useful alternatives are the ColorBrewer scales which have been hand tuned to work better for people with common types of color blindness. The two plots below look similar, but there is enough difference in the shades of red and green that the dots on the right can be distinguished even by people with red-green color blindness.

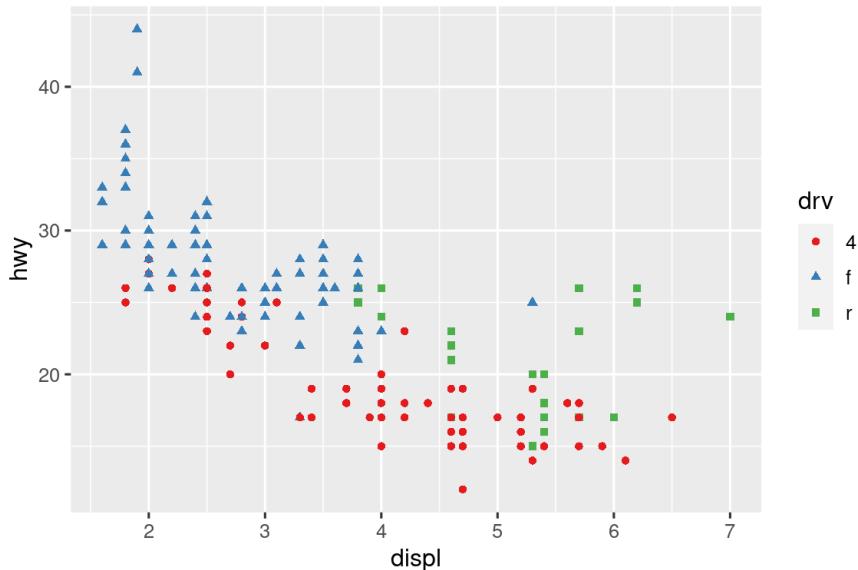

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = drv))  
  
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = drv)) +  
  scale_color_brewer(palette = "Set1")
```

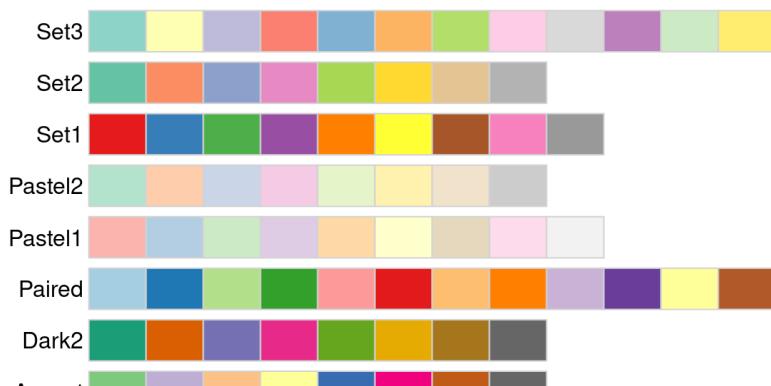

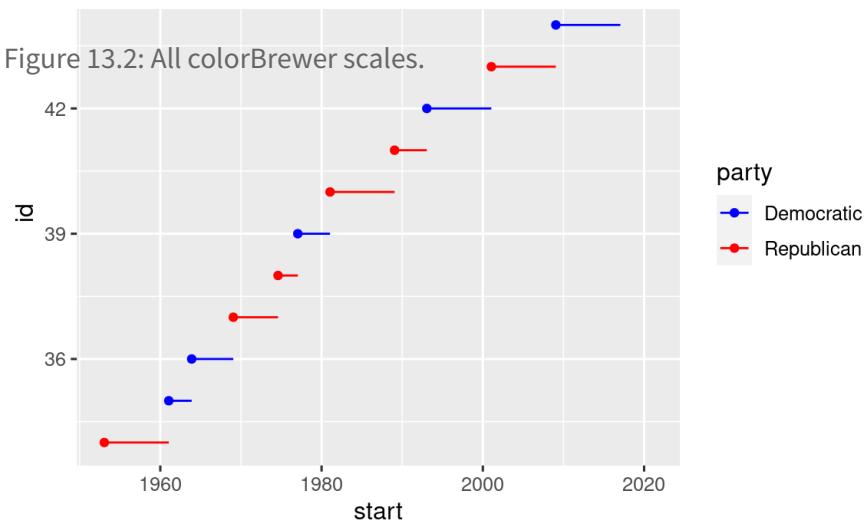

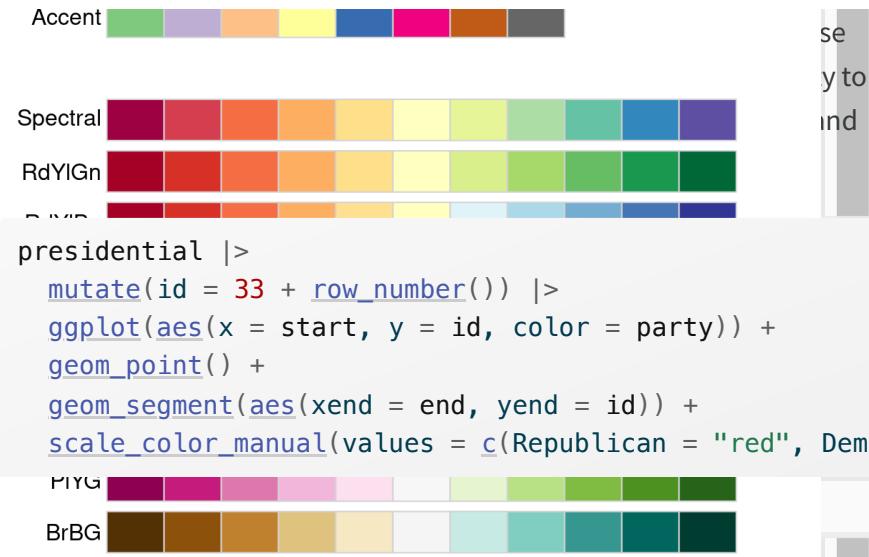

Don't forget simpler techniques. If there are just a few colors, you can add a redundant shape mapping. This will also help ensure your plot is interpretable in black and white.

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = drv, shape = drv)) +  
  scale_color_brewer(palette = "Set1")
```

The ColorBrewer scales are documented online at <https://colorbrewer2.org/> and made available in R via the **RColorBrewer** package, by Erich Neuwirth. [Figure 13.2](#) shows the complete list of all palettes. The sequential (top) and diverging (bottom) palettes are particularly useful if your categorical values are ordered, or have a “middle”. This often arises if you’ve used `cut()` to make a continuous variable into a categorical variable.

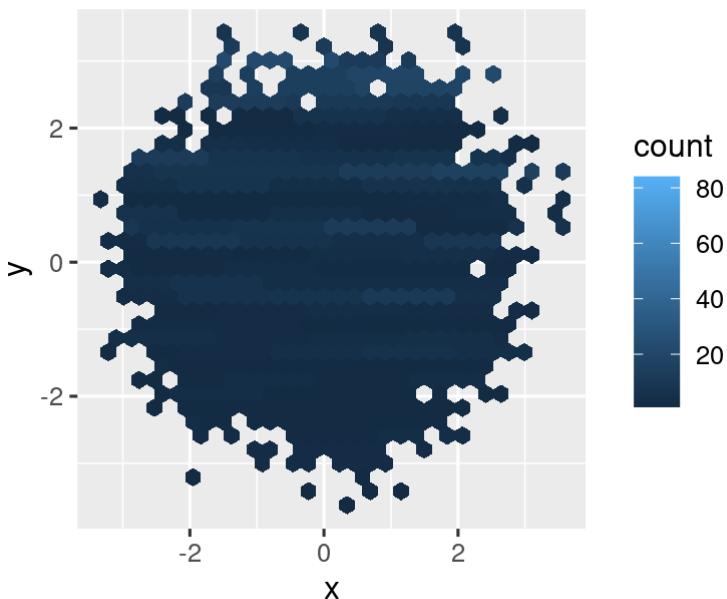

For continuous color, you can use the built-in `scale_color_gradient()` or `scale_fill_gradient()`. If you have a diverging scale, you can use `scale_color_gradient2()`. That allows you to give, for example, positive and negative values different

colors. That's sometimes also useful if you want to distinguish points above or below the mean.

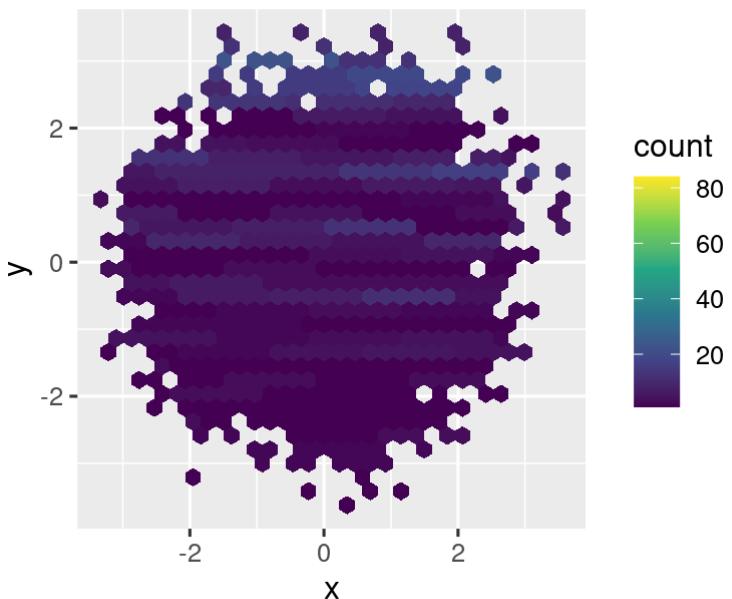

Another option is to use the viridis color scales. The designers, Nathaniel Smith and Stéfan van der Walt, carefully tailored continuous color schemes that are perceptible to people with various forms of color blindness as well as perceptually uniform in both color and black and white. These scales are available as continuous (`c`), discrete (`d`), and binned (`b`) palettes in ggplot2.

```
df <- tibble(  
  x = rnorm(10000),  
  y = rnorm(10000)  
)  
  
ggplot(df, aes(x, y)) +  
  geom_hex() +  
  coord_fixed() +  
  labs(title = "Default, continuous")  
  
ggplot(df, aes(x, y)) +  
  geom_hex() +  
  coord_fixed() +  
  scale_fill_viridis_c() +  
  labs(title = "Viridis, continuous")  
  
ggplot(df, aes(x, y)) +  
  geom_hex() +  
  coord_fixed() +  
  scale_fill_viridis_b() +  
  labs(title = "Viridis, binned")
```

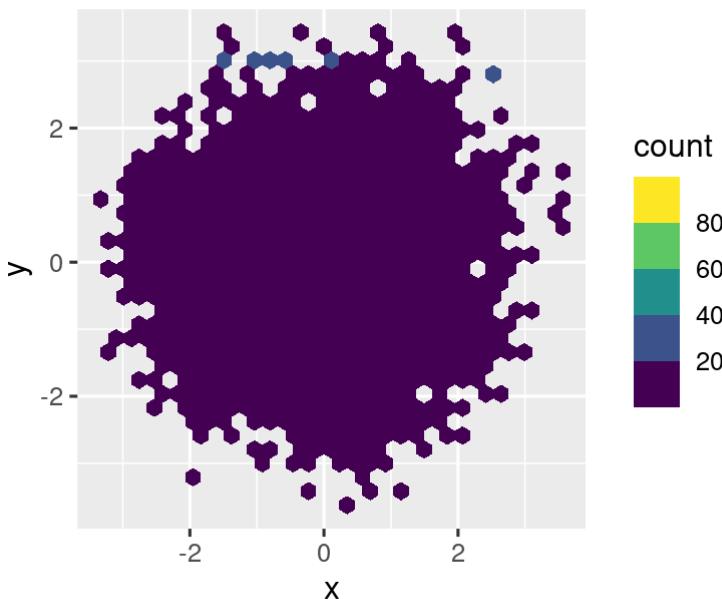

Default, continuous

Viridis, continuous

Viridis, binned

Note that all color scales come in two variety: `scale_color_x()` and `scale_fill_x()` for the `color` and `fill` aesthetics respectively (the color scales are available in both UK and US spellings).

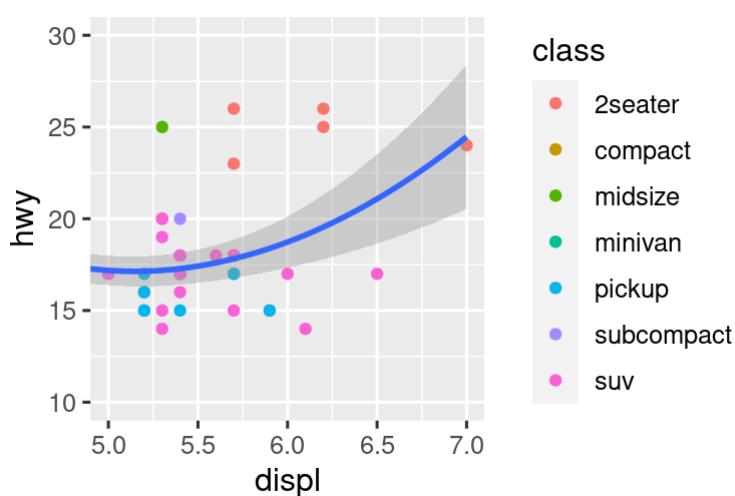

13.4.5 Zooming

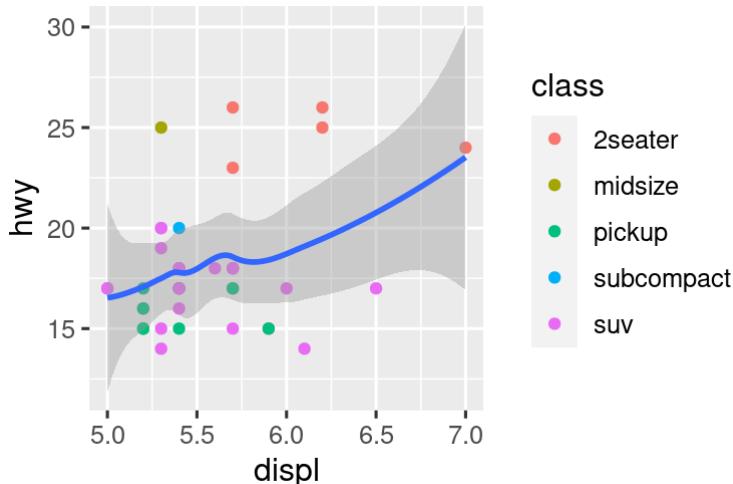

There are three ways to control the plot limits:

1. Adjusting what data are plotted.
2. Setting the limits in each scale.
3. Setting `xlim` and `ylim` in `coord_cartesian()`.

To zoom in on a region of the plot, it's generally best to use `coord_cartesian()`. Compare the following two plots:

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class)) +  
  geom_smooth() +  
  coord_cartesian(xlim = c(5, 7), ylim = c(10, 30))  
  
mpg |>  
  filter(displ >= 5, displ <= 7, hwy >= 10, hwy <= 30) |  
  ggplot(aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class)) +  
  geom_smooth()
```

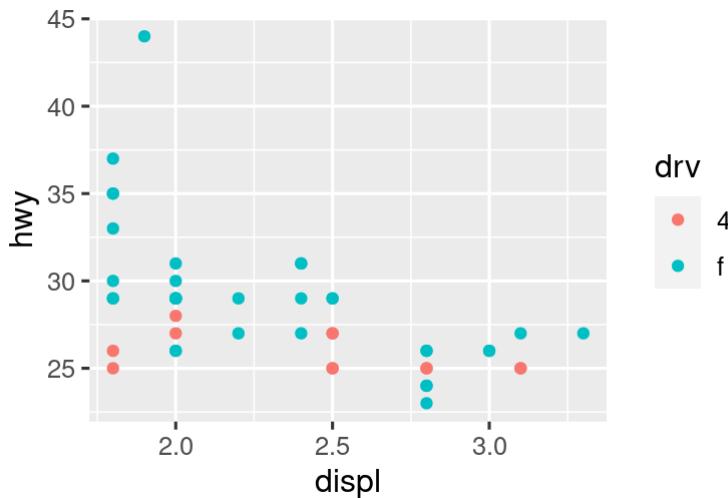

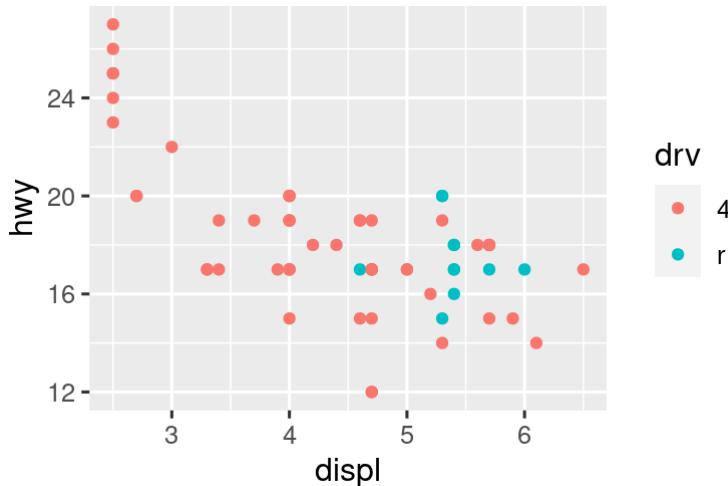

You can also set the `limits` on individual scales. Reducing the limits is basically equivalent to subsetting the data. It is generally more useful if you want *expand* the limits, for example, to match scales across different plots. For example, if we extract two classes of cars and plot them separately, it's difficult to compare the plots because all three scales (the x-axis, the y-axis, and the color aesthetic) have different ranges.

```
suv <- mpg |> filter(class == "suv")
compact <- mpg |> filter(class == "compact")

ggplot(suv, aes(x = displ, y = hwy, color = drv)) +
  geom_point()

ggplot(compact, aes(x = displ, y = hwy, color = drv)) +
  geom_point()
```

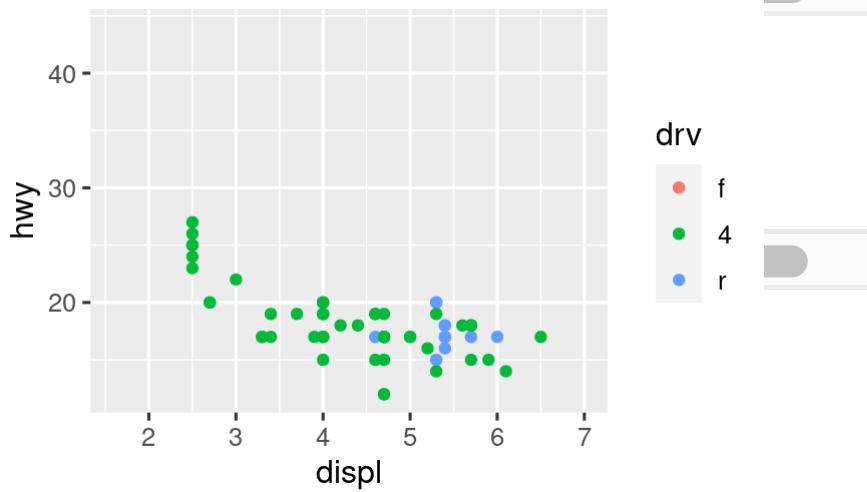

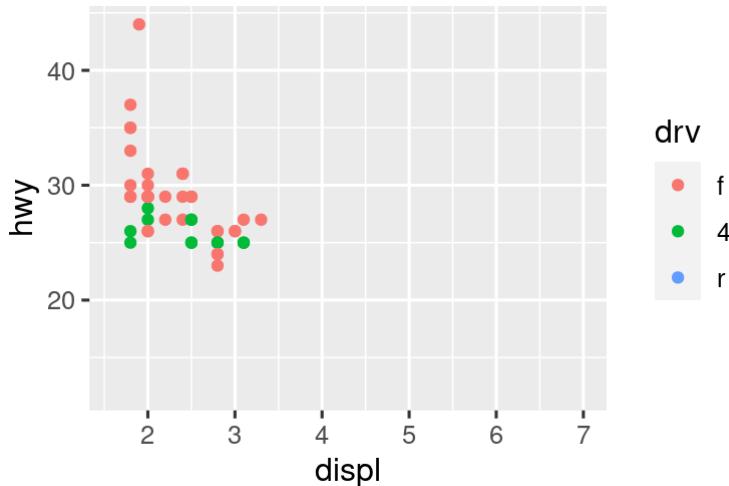

One way to overcome this problem is to share scales across multiple plots, training the scales with the `limits` of the full data.

```
x_scale <- scale_x_continuous(limits = range(mpg$displ))
y_scale <- scale_y_continuous(limits = range(mpg$hwy))
col_scale <- scale_color_discrete(limits = unique(mpg$drv))

ggplot(suv, aes(x = displ, y = hwy, color = drv)) +
geom_point() +
```

```
x_scale +  
y_scale +  
col_scale  
  
ggplot(compact, aes(x = displ, y = hwy, color = drv)) +  
  geom_point() +  
  x_scale +  
  y_scale +  
  col_scale
```

In this particular case, you could have simply used facetting, but this technique is useful more generally, if for instance, you want to spread plots over multiple pages of a report.

13.4.6 Exercises

1. Why doesn't the following code override the default scale?

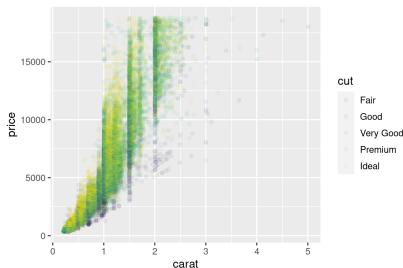

```
df <- tibble(  
  x = rnorm(10000),  
  y = rnorm(10000)  
)  
  
ggplot(df, aes(x, y)) +  
  geom_hex() +  
  scale_color_gradient(low = "white", high = "red")  
  coord_fixed()
```

2. What is the first argument to every scale? How does it compare to `labs()`?

3. Change the display of the presidential terms by:
- Combining the two variants shown above.
 - Improving the display of the y axis.
 - Labelling each term with the name of the president.
 - Adding informative plot labels.
 - Placing breaks every 4 years (this is trickier than it seems!).

4. Use `override.aes` to make the legend on the following plot easier to see.

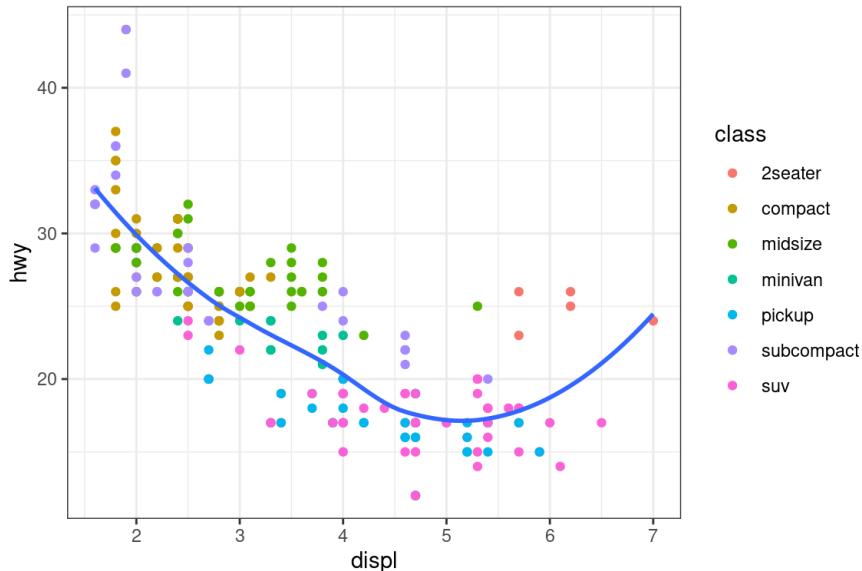

```
ggplot(diamonds, aes(x = carat, y = price)) +  
  geom_point(aes(color = cut), alpha = 1/20)
```

13.5 Themes

Finally, you can customize the non-data elements of your plot with a theme:

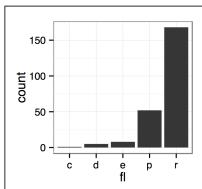

```
ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point(aes(color = class)) +  
  geom_smooth(se = FALSE) +  
  theme_bw()
```

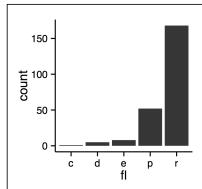

ggplot2 includes eight themes by default, as shown in [Figure 13.3](#). Many more are included in add-on packages like **ggtthemes** (<https://jrnold.github.io/ggtthemes>), by Jeffrey Arnold. You can also create your own themes, if you are trying to match a particular corporate or journal style.

Themes

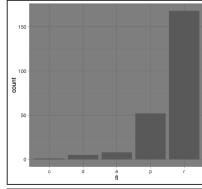

Theme functions change the appearance of your plot.

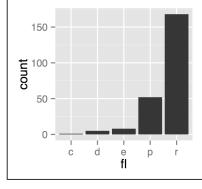

theme_bw()
White background
with grid lines

theme_light()
Light axes and grid
lines

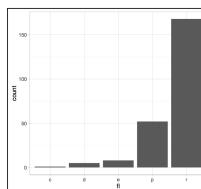

theme_classic()
Classic theme,
axes but no grid
lines

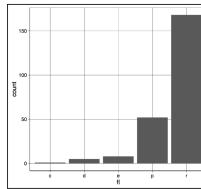

theme_dark()

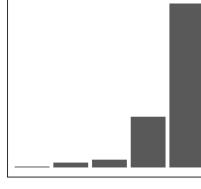

Dark background
for contrast

theme_linedraw()
Only black lines

theme_minimal()
Minimal theme, no
background

theme_gray()

Grey background
(default theme)

theme_void()
Empty theme, only
geoms are visible

Figure 13.3: The eight themes built-in to ggplot2.

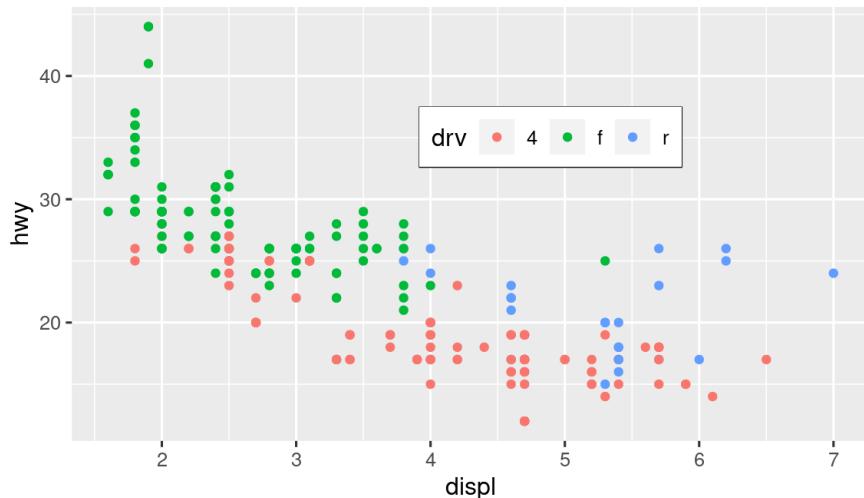

Many people wonder why the default theme has a gray background. This was a deliberate choice because it puts the data forward while still making the grid lines visible. The white grid lines are visible (which is important because they significantly aid position judgments), but they have little visual impact and we can easily tune them out. The grey background gives the plot a similar typographic color to the text, ensuring that the graphics fit in with the flow of a document without jumping out with a bright white background. Finally, the grey

background creates a continuous field of color which ensures that the plot is perceived as a single visual entity.

It's also possible to control individual components of each theme, like the size and color of the font used for the y axis. We've already seen that `legend.position` controls where the legend is drawn. There are many other aspects of the legend that can be customized with `theme()`. For example, in the plot below we change the direction of the legend as well as put a black border around it. A few other helpful `theme()` components are used to change the placement for format of the title and caption text.

```
ggplot(mpg, aes(x = displ, y = hwy, color = drv)) +  
  geom_point() +  
  labs(  
    title = "Highway mileage decreases as engine size increases",  
    caption = "Source: https://fueleconomy.gov."  
  ) +  
  theme(  
    legend.position = c(0.6, 0.7),  
    legend.direction = "horizontal",  
    legend.box.background = element_rect(color = "black"),  
    plot.title = element_text(face = "bold"),  
    plot.title.position = "plot",  
    plot.caption.position = "plot",  
    plot.caption = element_text(hjust = 0)  
  )
```

Highway mileage decreases as engine size increases

Source: <https://fueleconomy.gov>.

For an overview of all `theme()` components, see help with `?theme`.
The [ggplot2 book](#) is also a great place to go for the full details on theming.

13.5.1 Exercises

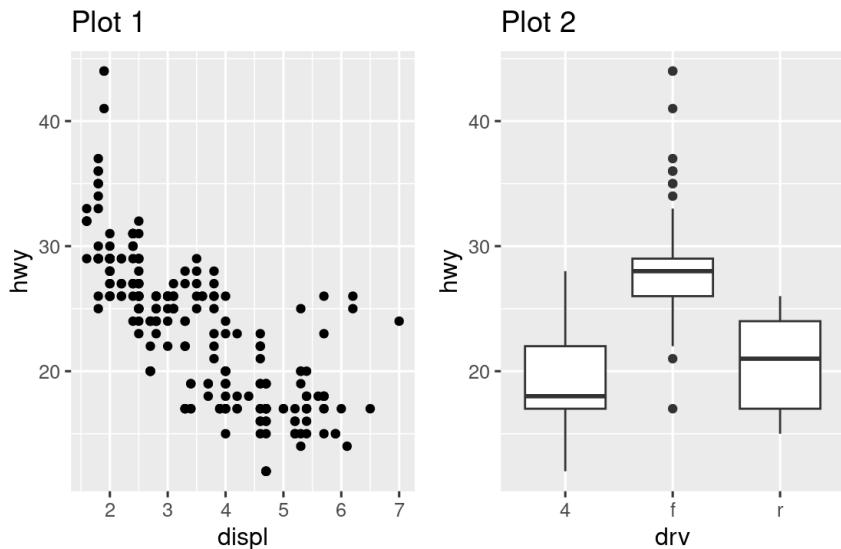

1. Pick a theme offered by the `ggthemes` package and apply it to the last plot you made.
2. Make the axis labels of your plot blue and bolded.

13.6 Layout

So far we talked about how to create and modify a single plot. What if you have multiple plots you want to lay out in a certain way? The `patchwork` package allows you to combine separate plots into the same graphic. We loaded this package earlier in the chapter.

To place two plots next to each other, you can simply add them to each other. Note that you first need to create the plots and save them as objects (in the following example they're called `p1` and `p2`). Then, you place them next to each other with `+`.

```
p1 <- ggplot(mpg, aes(x = displ, y = hwy)) +  
  geom_point() +  
  labs(title = "Plot 1")  
p2 <- ggplot(mpg, aes(x = drv, y = hwy)) +  
  geom_boxplot() +  
  labs(title = "Plot 2")  
p1 + p2
```

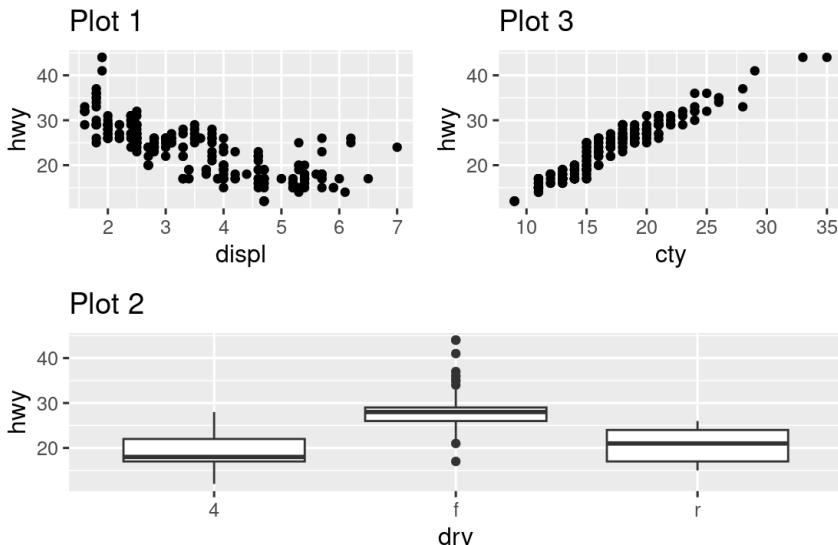

It's important to note that in the above code chunk we did not use a new function from the `patchwork` package. Instead, the package added a new functionality to the `+` operator.

You can also create arbitrary plot layouts with `patchwork`. In the following, `|` places the `p1` and `p3` next to each other and `/` moves `p2`

to the next line.

```
p3 <- ggplot(mpg, aes(x = cty, y = hwy)) +  
  geom_point() +  
  labs(title = "Plot 3")  
(p1 | p3) / p2
```

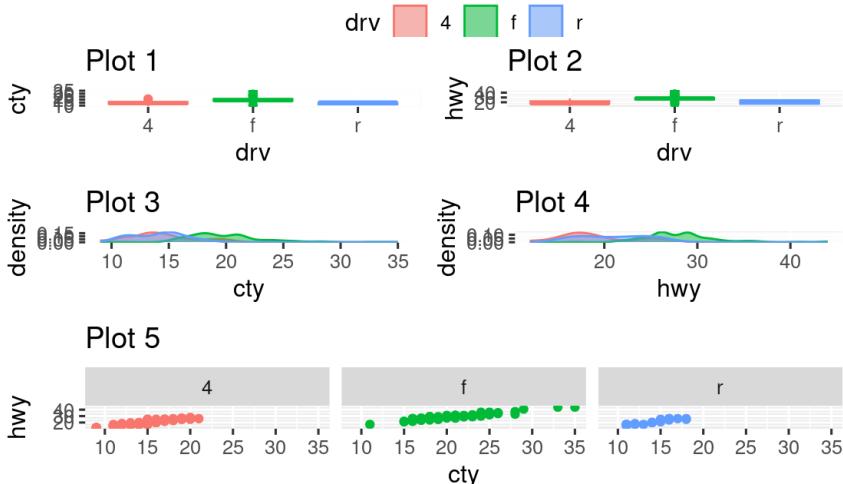

Additionally, patchwork allows you to collect legends from multiple plots into one common legend, customize the placement of the legend as well as dimensions of the plots, and add a common title, subtitle, caption, etc. to your plots. In the following, we have 5 plots. We have turned off the legends on the box plots and the scatterplot and collected the legends for the density plots at the top of the plot with `& theme(legend.position = "top")`. Note the use of the `&` operator here instead of the usual `+`. This is because we're modifying the theme for the patchwork plot as opposed to the individual ggplots. The legend is placed on top, inside the `guide_area()`. Finally, we have also customized the heights of the various components of our patchwork – the guide has a height of 1, the box plots 3, density plots 2, and the

faceted scatter plot 4. Patchwork divides up the area you have allotted for your plot using this scale and places the components accordingly.

```
p1 <- ggplot(mpg, aes(x = drv, y = cty, color = drv)) +  
  geom_boxplot(show.legend = FALSE) +  
  labs(title = "Plot 1")  
  
p2 <- ggplot(mpg, aes(x = drv, y = hwy, color = drv)) +  
  geom_boxplot(show.legend = FALSE) +  
  labs(title = "Plot 2")  
  
p3 <- ggplot(mpg, aes(x = cty, color = drv, fill = drv)) +  
  geom_density(alpha = 0.5) +  
  labs(title = "Plot 3")  
  
p4 <- ggplot(mpg, aes(x = hwy, color = drv, fill = drv)) +  
  geom_density(alpha = 0.5) +  
  labs(title = "Plot 4")  
  
p5 <- ggplot(mpg, aes(x = cty, y = hwy, color = drv)) +  
  geom_point(show.legend = FALSE) +  
  facet_wrap(~drv) +  
  labs(title = "Plot 5")  
  
(guide_area() / (p1 + p2) / (p3 + p4) / p5) +  
  plot_annotation(  
    title = "City and highway mileage for cars with diff  
    caption = "Source: Source: https://fueleconomy.gov."  
  ) +  
  plot_layout(  
    guides = "collect",  
    heights = c(1, 3, 2, 4)  
  ) &  
  theme(legend.position = "bottom")
```

City and highway mileage for cars with different drive trains

Source: <https://fueleconomy.gov>.

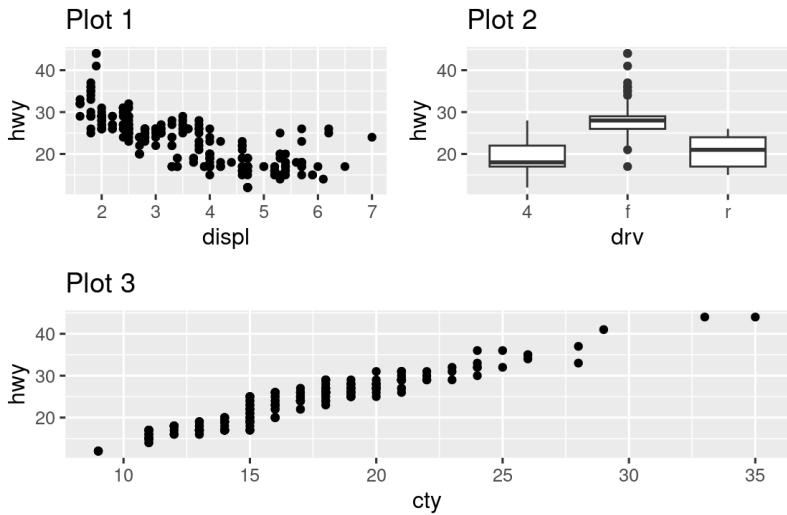

If you'd like to learn more about combining and layout out multiple plots with patchwork, we recommend looking through the guides on the package website: <https://patchwork.data-imaginist.com>.

13.6.1 Exercises

1. What happens if you omit the parentheses in the following plot layout. Can you explain why this happens?

```
p1 <- ggplot(mpg, aes(x = displ, y = hwy)) +
  geom_point() +
  labs(title = "Plot 1")
p2 <- ggplot(mpg, aes(x = drv, y = hwy)) +
  geom_boxplot() +
  labs(title = "Plot 2")
p3 <- ggplot(mpg, aes(x = cty, y = hwy)) +
  geom_point() +
  labs(title = "Plot 3")

(p1 | p2) / p3
```

2. Using the three plots from the previous exercise, recreate the following patchwork.

Fig. A:

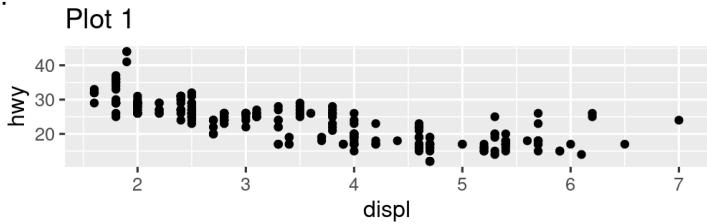

Fig. B:

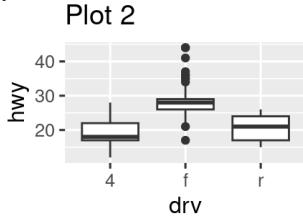

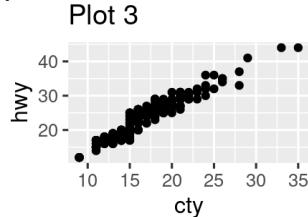

Fig. C:

13.7 Summary

In this chapter you've learned about adding plot labels such as title, subtitle, caption as well as modifying default axis labels, using annotation to add informational text to your plot or to highlight specific data points, customizing the axis scales, and changing the theme of your plot. You've also learned about combining multiple plots in a single graph using both simple and complex plot layouts.

While you've so far learned about how to make many different types of plots and how to customize them using a variety of techniques, we've barely scratched the surface of what you can create with ggplot2. If you want to get a comprehensive understanding of ggplot2, we recommend reading the book, *ggplot2: Elegant Graphics for Data Analysis*. Other useful resources are the *R Graphics Cookbook* by Winston Chang and *Fundamentals of Data Visualization* by Claus Wilke.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with Quarto.

Transform

>

The second part of the book was a deep dive into data visualization. In this part of the book, you'll learn about the most important types of variables that you'll encounter inside a data frame and learn the tools you can use to work with them.

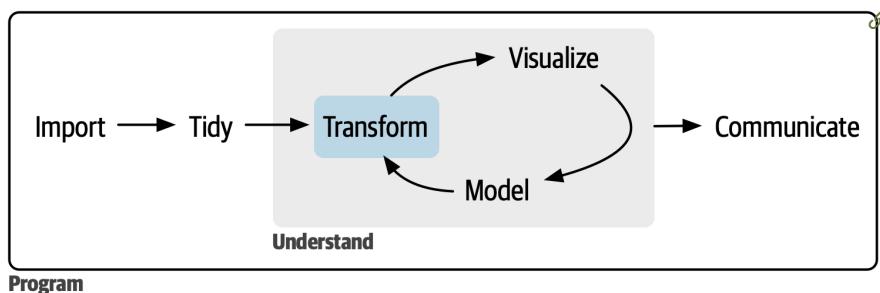

Figure 1: The options for data transformation depends heavily on the type of data involved, the subject of this part of the book.

You can read these chapters as you need them; they're designed to be largely standalone so that they can be read out of order.

- [Chapter 14](#) teaches you about logical vectors. These are simplest type of vector, but are extremely powerful. You'll learn how to create them with numeric comparisons, how to combine them with Boolean algebra, how to use them in summaries, and how to use them for condition transformations.
- [Chapter 15](#) dives into tools for vectors of numbers, the powerhouse of data science. You'll learn more about counting and a bunch of important transformation and summary functions.

- [Chapter 16](#) will give you the tools to work with strings: you'll slice them, you'll dice them, and you'll stick them back together again. This chapter mostly focuses on the stringr package, but you'll also learn some more tidyverse functions devoted to extracting data from strings.
- [Chapter 17](#) introduces you to regular expressions, a powerful tool for manipulating strings. This chapter will take you from thinking that a cat walked over your keyboard to reading and writing complex string patterns.
- [Chapter 18](#) introduces factors: the data type that R uses to store categorical data. You use a factor when variable has a fixed set of possible values, or when you want to use a non-alphabetical ordering of a string.
- [Chapter 19](#) will give you the key tools for working with dates and date-times. Unfortunately, the more you learn about date-times, the more complicated they seem to get, but with the help of the lubridate package, you'll learn to how to overcome the most common challenges.
- [Chapter 20](#) discusses missing values in depth. We've discussed them a couple of times in isolation, but now it's time to discuss them holistically, helping you come to grips with the difference between implicit and explicit missing values, and how and why you might convert between them.
- [Chapter 21](#) finishes up this part of the book by giving you tools to join two (or more) data frames together. Learning about joins will force you to grapple with the idea of keys, and think about how you identify each row in a dataset.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built
with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

14.1 Introduction

In this chapter, you’ll learn tools for working with logical vectors. Logical vectors are the simplest type of vector because each element can only be one of three possible values: `TRUE`, `FALSE`, and `NA`. It’s relatively rare to find logical vectors in your raw data, but you’ll create and manipulate them in the course of almost every analysis.

We’ll begin by discussing the most common way of creating logical vectors: with numeric comparisons. Then you’ll learn about how you can use Boolean algebra to combine different logical vectors, as well as some useful summaries. We’ll finish off with `if_else()` and `case_when()`, two useful functions for making conditional changes powered by logical vectors.

14.1.1 Prerequisites

Most of the functions you’ll learn about in this chapter are provided by base R, so we don’t need the tidyverse, but we’ll still load it so we can use `mutate()`, `filter()`, and friends to work with data frames. We’ll also continue to draw examples from the `nycflights13` dataset.

```
library(tidyverse)
library(nycflights13)
```

However, as we start to cover more tools, there won't always be a perfect real example. So we'll start making up some dummy data with `c()`:

```
x <- c(1, 2, 3, 5, 7, 11, 13)
x * 2
#> [1] 2 4 6 10 14 22 26
```

This makes it easier to explain individual functions at the cost of making it harder to see how it might apply to your data problems. Just remember that any manipulation we do to a free-floating vector, you can do to a variable inside a data frame with `mutate()` and friends.

```
df <- tibble(x)
df |>
  mutate(y = x * 2)
#> # A tibble: 7 × 2
#>       x     y
#>   <dbl> <dbl>
#> 1     1     2
#> 2     2     4
#> 3     3     6
#> 4     5    10
#> 5     7    14
#> 6    11    22
#> # ... with 1 more row
```

14.2 Comparisons

A very common way to create a logical vector is via a numeric comparison with `<`, `<=`, `>`, `>=`, `!=`, and `==`. So far, we've mostly created logical variables transiently within `filter()` — they are computed, used, and then thrown away. For example, the following filter finds all daytime departures that leave roughly on time:

```
flights |>
  filter(dep_time > 600 & dep_time < 2000 & abs(arr_delay) < 20)
#> # A tibble: 172,286 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time
#>   <int> <int> <int>     <dbl>        <dbl>      <dbl>      <dbl>
#> 1 2013     1     1       601        600         1        844
#> 2 2013     1     1       602        610        -8        812
#> 3 2013     1     1       602        605        -3        821
#> 4 2013     1     1       606        610        -4        858
#> 5 2013     1     1       606        610        -4        837
#> 6 2013     1     1       607        607         0        858
#> # ... with 172,280 more rows, 9 more variables: flight <chr>,
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>,
#> #   minute <dbl>, time_hour <dttm>, and abbreviated version
#> #   `^`sched_dep_time, `^`dep_delay, `^`arr_time, `^`sched_ar
```

It's useful to know that this is a shortcut and you can explicitly create the underlying logical variables with `mutate()`:

```
flights |>
  mutate(
    daytime = dep_time > 600 & dep_time < 2000,
    approx_ontime = abs(arr_delay) < 20,
    .keep = "used"
  )
#> # A tibble: 336,776 × 4
#>   dep_time arr_delay daytime approx_ontime
#>       <dbl>      <dbl>     <lgl>      <lgl>
```

```
#> 1      517      11 FALSE  TRUE
#> 2      533      20 FALSE FALSE
#> 3      542      33 FALSE FALSE
#> 4      544     -18 FALSE  TRUE
#> 5      554     -25 FALSE FALSE
#> 6      554      12 FALSE  TRUE
#> # ... with 336,770 more rows
```

This is particularly useful for more complicated logic because naming the intermediate steps makes it easier to both read your code and check that each step has been computed correctly.

All up, the initial filter is equivalent to:

```
flights |>
  mutate(
    daytime = dep_time > 600 & dep_time < 2000,
    approx_ontime = abs(arr_delay) < 20,
  ) |>
  filter(daytime & approx_ontime)
```

14.2.1 Floating point comparison

Beware of using `==` with numbers. For example, it looks like this vector contains the numbers 1 and 2:

```
x <- c(1 / 49 * 49, sqrt(2) ^ 2)
x
#> [1] 1 2
```

But if you test them for equality, you get `FALSE`:

```
x == c(1, 2)
#> [1] FALSE FALSE
```

What's going on? Computers store numbers with a fixed number of decimal places so there's no way to exactly represent $1/49$ or $\sqrt{2}$ and subsequent computations will be very slightly off. We can see the exact values by calling `print()` with the `digits`¹ argument:

```
print(x, digits = 16)
#> [1] 0.9999999999999999 2.0000000000000004
```

You can see why R defaults to rounding these numbers; they really are very close to what you expect.

Now that you've seen why `==` is failing, what can you do about it? One option is to use `dplyr::near()` which ignores small differences:

```
near(x, c(1, 2))
#> [1] TRUE TRUE
```

14.2.2 Missing values

Missing values represent the unknown so they are “contagious”: almost any operation involving an unknown value will also be unknown:

```
NA > 5
#> [1] NA
10 == NA
#> [1] NA
```

The most confusing result is this one:

```
NA == NA
#> [1] NA
```

It's easiest to understand why this is true if we artificially supply a little more context:

```
# Let x be Mary's age. We don't know how old she is.  
x <- NA  
  
# Let y be John's age. We don't know how old he is.  
y <- NA  
  
# Are John and Mary the same age?  
x == y  
#> [1] NA  
# We don't know!
```

So if you want to find all flights where `dep_time` is missing, the following code doesn't work because `dep_time == NA` will yield `NA` for every single row, and `filter()` automatically drops missing values:

```
flights |>  
  filter(dep_time == NA)  
#> # A tibble: 0 × 19  
#> # ... with 19 variables: year <int>, month <int>, day <  
#> #   sched_dep_time <int>, dep_delay <dbl>, arr_time <  
#> #   sched_arr_time <int>, arr_delay <dbl>, carrier <c  
#> #   tailnum <chr>, origin <chr>, dest <chr>, air_time  
#> #   hour <dbl>, minute <dbl>, time_hour <dttm>
```

Instead we'll need a new tool: `is.na()`.

14.2.3 `is.na()`

`is.na(x)` works with any type of vector and returns `TRUE` for missing values and `FALSE` for everything else:

```
is.na(c(TRUE, NA, FALSE))  
#> [1] FALSE TRUE FALSE  
is.na(c(1, NA, 3))  
#> [1] FALSE TRUE FALSE  
is.na(c("a", NA, "b"))  
#> [1] FALSE TRUE FALSE
```

We can use `is.na()` to find all the rows with a missing `dep_time`:

```
flights |>  
  filter(is.na(dep_time))  
#> # A tibble: 8,255 × 19  
#>   year month   day dep_time sched_dep_time dep_delay arr_time arr_delay  
#>   <int> <int> <int> <dbl> <dbl> <dbl> <dbl> <dbl>  
#> 1 2013     1     1      NA      1630      NA      NA      NA  
#> 2 2013     1     1      NA      1935      NA      NA      NA  
#> 3 2013     1     1      NA      1500      NA      NA      NA  
#> 4 2013     1     1      NA       600      NA      NA      NA  
#> 5 2013     1     2      NA      1540      NA      NA      NA  
#> 6 2013     1     2      NA      1620      NA      NA      NA  
#> # ... with 8,249 more rows, 9 more variables: flight <i>  
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>,  
#> #   minute <dbl>, time_hour <dttm>, and abbreviated version <chr>  
#> #   <sup>1</sup>sched_dep_time, <sup>2</sup>dep_delay, <sup>3</sup>arr_time, <sup>4</sup>sched_ar
```

`is.na()` can also be useful in `arrange()`. `arrange()` usually puts all the missing values at the end but you can override this default by first sorting by `is.na()`:

```
flights |>  
  filter(month == 1, day == 1) |>  
  arrange(is.na(dep_time))  
#> # A tibble: 842 × 19
```

```

#>   year month   day dep_time sched_dep_time1 dep_delay2 arr_time3
#>   <int> <int> <int>     <int>      <int>    <dbl>     <int>
#> 1 2013     1     1      517        515       2        830
#> 2 2013     1     1      533        529       4        850
#> 3 2013     1     1      542        540       2        923
#> 4 2013     1     1      544        545      -1       1004
#> 5 2013     1     1      554        600      -6       812
#> 6 2013     1     1      554        558      -4       740
#> # ... with 836 more rows, 9 more variables: flight <int>
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>
#> #   minute <dbl>, time_hour <dttm>, and abbreviated version <chr>
#> #   1sched_dep_time, 2dep_delay, 3arr_time, 4sched_arr_time

flights |>
  filter(month == 1, day == 1) |>
  arrange(desc(is.na(dep_time)), dep_time)
#> # A tibble: 842 × 19
#>   year month   day dep_time sched_dep_time1 dep_delay2 arr_time3
#>   <int> <int> <int>     <int>      <int>    <dbl>     <int>
#> 1 2013     1     1       NA        1630       NA       NA
#> 2 2013     1     1       NA        1935       NA       NA
#> 3 2013     1     1       NA        1500       NA       NA
#> 4 2013     1     1       NA        600        NA       NA
#> 5 2013     1     1      517        515       2        830
#> 6 2013     1     1      533        529       4        850
#> # ... with 836 more rows, 9 more variables: flight <int>
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>
#> #   minute <dbl>, time_hour <dttm>, and abbreviated version <chr>
#> #   1sched_dep_time, 2dep_delay, 3arr_time, 4sched_arr_time

```

We'll come back to cover missing values in more depth in [Chapter 20](#).

14.2.4 Exercises

1. How does `dplyr::near()` work? Type `near` to see the source code.
2. Use `mutate()`, `is.na()`, and `count()` together to describe how the missing values in `dep_time`, `sched_dep_time` and `dep_delay` are connected.

14.3 Boolean algebra

Once you have multiple logical vectors, you can combine them together using Boolean algebra. In R, `&` is “and”, `|` is “or”, `!` is “not”, and `xor()` is exclusive or². [Figure 14.1](#) shows the complete set of Boolean operations and how they work.

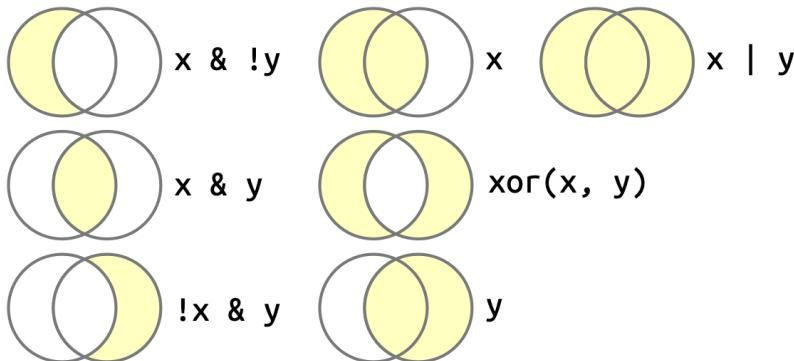

Figure 14.1: The complete set of boolean operations. `x` is the left-hand circle, `y` is the right-hand circle, and the shaded region show which parts each operator selects.

As well as `&` and `|`, R also has `&&` and `||`. Don’t use them in `dplyr` functions! These are called short-circuiting operators and only ever return a single `TRUE` or `FALSE`. They’re important for programming, not data science.

14.3.1 Missing values

The rules for missing values in Boolean algebra are a little tricky to explain because they seem inconsistent at first glance:

```
df <- tibble(x = c(TRUE, FALSE, NA))

df |>
  mutate(
    and = x & NA,
    or = x | NA
  )
#> # A tibble: 3 × 3
#>   x     and   or
#>   <lgl> <lgl> <lgl>
#> 1 TRUE  NA    TRUE
#> 2 FALSE FALSE NA
#> 3 NA    NA    NA
```

To understand what's going on, think about `NA | TRUE`. A missing value in a logical vector means that the value could either be `TRUE` or `FALSE`. `TRUE | TRUE` and `FALSE | TRUE` are both `TRUE`, so `NA | TRUE` must also be `TRUE`. Similar reasoning applies with `NA & FALSE`.

14.3.2 Order of operations

Note that the order of operations doesn't work like English. Take the following code that finds all flights that departed in November or December:

```
flights |>
  filter(month == 11 | month == 12)
```

You might be tempted to write it like you'd say in English: "Find all flights that departed in November or December."

```
flights |>
  filter(month == 11 | 12)
#> # A tibble: 336,776 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time arr_delay
#>   <int> <int> <int>     <dbl>        <dbl>      <dbl>     <dbl>
#> 1 2013     1     1       517         515        2        830
#> 2 2013     1     1       533         529        4        850
#> 3 2013     1     1       542         540        2        923
#> 4 2013     1     1       544         545       -1       1004
#> 5 2013     1     1       554         600       -6        812
#> 6 2013     1     1       554         558       -4        746
#> # ... with 336,770 more rows, 9 more variables: flight
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   `¹sched_dep_time`, `²dep_delay`, `³arr_time`, `⁴sched_ar
```

This code doesn't error but it also doesn't seem to have worked. What's going on? Here, R first evaluates `month == 11` creating a logical vector, which we call `nov`. It computes `nov | 12`. When you use a number with a logical operator it converts everything apart from 0 to `TRUE`, so this is equivalent to `nov | TRUE` which will always be `TRUE`, so every row will be selected:

```
flights |>
  mutate(
    nov = month == 11,
    final = nov | 12,
    .keep = "used"
  )
#> # A tibble: 336,776 × 3
#>   month nov   final
#>   <int> <lgl> <lgl>
#> 1     1 FALSE TRUE
```

```
#> 2      1 FALSE TRUE
#> 3      1 FALSE TRUE
#> 4      1 FALSE TRUE
#> 5      1 FALSE TRUE
#> 6      1 FALSE TRUE
#> # ... with 336,770 more rows
```

14.3.3 %in%

An easy way to avoid the problem of getting your ==s and | s in the right order is to use %in%. x %in% y returns a logical vector the same length as x that is TRUE whenever a value in x is anywhere in y .

```
1:12 %in% c(1, 5, 11)
#> [1] TRUE FALSE FALSE FALSE  TRUE FALSE FALSE FALSE
letters[1:10] %in% c("a", "e", "i", "o", "u")
#> [1] TRUE FALSE FALSE FALSE  TRUE FALSE FALSE FALSE
```

So to find all flights in November and December we could write:

```
flights |>
  filter(month %in% c(11, 12))
```

Note that %in% obeys different rules for NA to ==, as NA %in% NA is TRUE .

```
c(1, 2, NA) == NA
#> [1] NA NA NA
c(1, 2, NA) %in% NA
#> [1] FALSE FALSE  TRUE
```

This can make for a useful shortcut:

```
flights |>
  filter(dep_time %in% c(NA, 0800))
#> # A tibble: 8,803 × 19
#>   year month   day dep_time sched_dep_time1 dep_delay2 arr_time3
#>   <int> <int> <int>     <int>      <int>     <dbl>     <int>
#> 1 2013     1     1       800        800       0    1022
#> 2 2013     1     1       800        810      -10     949
#> 3 2013     1     1        NA       1630       NA      NA
#> 4 2013     1     1        NA       1935       NA      NA
#> 5 2013     1     1        NA       1500       NA      NA
#> 6 2013     1     1        NA       600        NA      NA
#> # ... with 8,797 more rows, 9 more variables: flight <int>,
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance <dbl>,
#> #   minute <dbl>, time_hour <dttm>, and abbreviated version
#> #   1sched_dep_time, 2dep_delay, 3arr_time, 4sched_arr_time
```

14.3.4 Exercises

1. Find all flights where `arr_delay` is missing but `dep_delay` is not.
Find all flights where neither `arr_time` nor `sched_arr_time` are missing, but `arr_delay` is.
2. How many flights have a missing `dep_time`? What other variables are missing in these rows? What might these rows represent?
3. Assuming that a missing `dep_time` implies that a flight is cancelled, look at the number of cancelled flights per day. Is there a pattern? Is there a connection between the proportion of cancelled flights and the average delay of non-cancelled flights?

14.4 Summaries

The following sections describe some useful techniques for summarizing logical vectors. As well as functions that only work specifically with logical vectors, you can also use functions that work with numeric vectors.

14.4.1 Logical summaries

There are two main logical summaries: `any()` and `all()`. `any(x)` is the equivalent of `|`; it'll return `TRUE` if there are any `TRUE`'s in `x`. `all(x)` is equivalent of `&`; it'll return `TRUE` only if all values of `x` are `TRUE`'s. Like all summary functions, they'll return `NA` if there are any missing values present, and as usual you can make the missing values go away with `na.rm = TRUE`.

For example, we could use `all()` to find out if there were days where every flight was delayed:

```
flights |>
  group_by(year, month, day) |>
  summarize(
    all_delayed = all(arr_delay >= 0, na.rm = TRUE),
    any_delayed = any(arr_delay >= 0, na.rm = TRUE),
    .groups = "drop"
  )
#> # A tibble: 365 × 5
#>   year month   day all_delayed any_delayed
#>   <int> <int> <int> <lgl>      <lgl>
#> 1  2013     1     1 FALSE      TRUE
#> 2  2013     1     2 FALSE      TRUE
#> 3  2013     1     3 FALSE      TRUE
#> 4  2013     1     4 FALSE      TRUE
#> 5  2013     1     5 FALSE      TRUE
#> 6  2013     1     6 FALSE      TRUE
#> # ... with 359 more rows
```

In most cases, however, `any()` and `all()` are a little too crude, and it would be nice to be able to get a little more detail about how many values are `TRUE` or `FALSE`. That leads us to the numeric summaries.

14.4.2 Numeric summaries of logical vectors

When you use a logical vector in a numeric context, `TRUE` becomes 1 and `FALSE` becomes 0. This makes `sum()` and `mean()` very useful with logical vectors because `sum(x)` will give the number of `TRUE`s and `mean(x)` the proportion of `TRUE`s. That lets us see the distribution of delays across the days of the year as shown in [Figure 14.2](#)

```
flights |>
  group_by(year, month, day) |>
  summarize(
    prop_delayed = mean(arr_delay > 0, na.rm = TRUE),
    .groups = "drop"
  ) |>
  ggplot(aes(x = prop_delayed)) +
  geom_histogram(binwidth = 0.05)
```

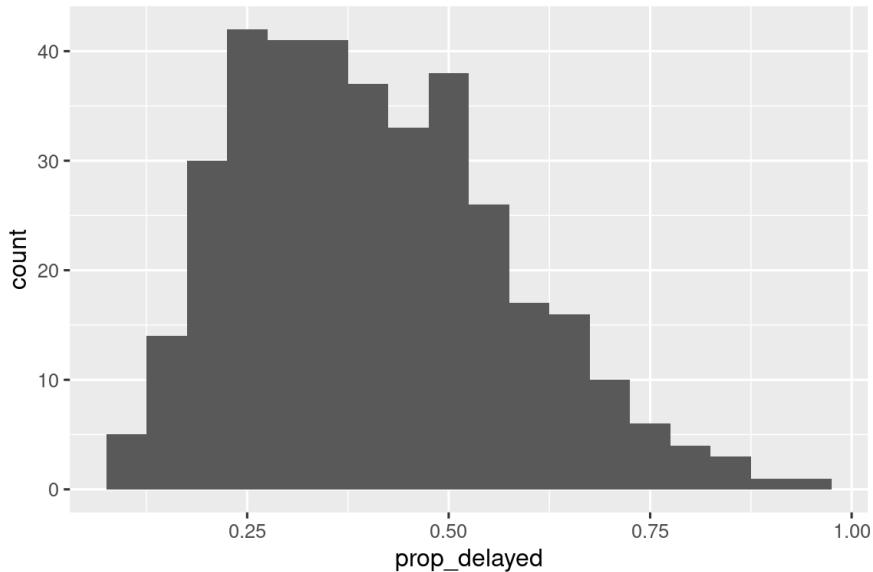

Figure 14.2: A histogram showing the proportion of delayed flights each day.

Or we could ask: “How many flights left before 5am?”, which are often flights that were delayed from the previous day:

```
flights |>
  group_by(year, month, day) |>
  summarize(
    n_early = sum(dep_time < 500, na.rm = TRUE),
    .groups = "drop"
  ) |>
  arrange(desc(n_early))
#> # A tibble: 365 × 4
#>   year month   day n_early
#>   <int> <int> <int>   <int>
#> 1  2013     6     28     32
#> 2  2013     4     10     30
#> 3  2013     7     28     30
#> 4  2013     3     18     29
```

```
#> 5 2013    7    7    29  
#> 6 2013    7   10    29  
#> # ... with 359 more rows
```

14.4.3 Logical subsetting

There's one final use for logical vectors in summaries: you can use a logical vector to filter a single variable to a subset of interest. This makes use of the base `[` (pronounced subset) operator, which you'll learn more about in [Section 29.1](#).

Imagine we wanted to look at the average delay just for flights that were actually delayed. One way to do so would be to first filter the flights and then calculate the average delay:

```
flights |>  
  filter(arr_delay > 0) |>  
  group_by(year, month, day) |>  
  summarize(  
    behind = mean(arr_delay),  
    n = n(),  
    .groups = "drop"  
  )  
#> # A tibble: 365 × 5  
#>   year month   day behind     n  
#>   <int> <int> <int>  <dbl> <int>  
#> 1 2013     1     1    32.5    461  
#> 2 2013     1     2    32.0    535  
#> 3 2013     1     3    27.7    460  
#> 4 2013     1     4    28.3    297  
#> 5 2013     1     5    22.6    238  
#> 6 2013     1     6    24.4    381  
#> # ... with 359 more rows
```

This works, but what if we wanted to also compute the average delay for flights that arrived early? We'd need to perform a separate filter step, and then figure out how to combine the two data frames together³.

Instead you could use `[` to perform an inline filtering:

`arr_delay[arr_delay > 0]` will yield only the positive arrival delays.

This leads to:

```
flights |>
  group_by(year, month, day) |>
  summarize(
    behind = mean(arr_delay[arr_delay > 0], na.rm = TRUE),
    ahead = mean(arr_delay[arr_delay < 0], na.rm = TRUE),
    n = n(),
    .groups = "drop"
  )
#> # A tibble: 365 × 6
#>   year month   day behind ahead     n
#>   <int> <int> <int>  <dbl> <dbl> <int>
#> 1  2013     1     1    32.5 -12.5   842
#> 2  2013     1     2    32.0 -14.3   943
#> 3  2013     1     3    27.7 -18.2   914
#> 4  2013     1     4    28.3 -17.0   915
#> 5  2013     1     5    22.6 -14.0   720
#> 6  2013     1     6    24.4 -13.6   832
#> # ... with 359 more rows
```

Also note the difference in the group size: in the first chunk `n()` gives the number of delayed flights per day; in the second, `n()` gives the total number of flights.

14.4.4 Exercises

1. What will `sum(is.na(x))` tell you? How about `mean(is.na(x))`?

2. What does `prod()` return when applied to a logical vector? What logical summary function is it equivalent to? What does `min()` return when applied to a logical vector? What logical summary function is it equivalent to? Read the documentation and perform a few experiments.

14.5 Conditional transformations

One of the most powerful features of logical vectors are their use for conditional transformations, i.e. doing one thing for condition x, and something different for condition y. There are two important tools for this: `if_else()` and `case_when()`.

14.5.1 `if_else()`

If you want to use one value when a condition is `TRUE` and another value when it's `FALSE`, you can use `dplyr::if_else()`⁴. You'll always use the first three argument of `if_else()`. The first argument, `condition`, is a logical vector, the second, `true`, gives the output when the condition is true, and the third, `false`, gives the output if the condition is false.

Let's begin with a simple example of labeling a numeric vector as either “+ve” or “-ve”:

```
x <- c(-3:3, NA)
if_else(x > 0, "+ve", "-ve")
#> [1] "-ve" "-ve" "-ve" "-ve" "+ve" "+ve" "+ve" NA
```

There's an optional fourth argument, `missing` which will be used if the input is `NA`:

```
if_else(x > 0, "+ve", "-ve", "??")  
#> [1] "-ve" "-ve" "-ve" "-ve" "+ve" "+ve" "+ve" "??"
```

You can also use vectors for the the `true` and `false` arguments. For example, this allows us to create a minimal implementation of `abs()`:

```
if_else(x < 0, -x, x)  
#> [1] 3 2 1 0 1 2 3 NA
```

So far all the arguments have used the same vectors, but you can of course mix and match. For example, you could implement a simple version of `coalesce()` like this:

```
x1 <- c(NA, 1, 2, NA)  
y1 <- c(3, NA, 4, 6)  
if_else(is.na(x1), y1, x1)  
#> [1] 3 1 2 6
```

You might have noticed a small infelicity in our labeling example above: zero is neither positive nor negative. We could resolve this by adding an additional `if_else()`:

```
if_else(x == 0, "0", if_else(x < 0, "-ve", "+ve"), "??")  
#> [1] "-ve" "-ve" "-ve" "0" "+ve" "+ve" "+ve" "??"
```

This is already a little hard to read, and you can imagine it would only get harder if you have more conditions. Instead, you can switch to `dplyr::case_when()`.

14.5.2 `case_when()`

dplyr's `case_when()` is inspired by SQL's CASE statement and provides a flexible way of performing different computations for different conditions. It has a special syntax that unfortunately looks like nothing else you'll use in the tidyverse. It takes pairs that look like `condition ~ output`. `condition` must be a logical vector; when it's `TRUE`, `output` will be used.

This means we could recreate our previous nested `if_else()` as follows:

```
case_when(  
  x == 0 ~ "0",  
  x < 0 ~ "-ve",  
  x > 0 ~ "+ve",  
  is.na(x) ~ "???")  
#> [1] "-ve" "-ve" "-ve" "0"    "+ve" "+ve" "+ve" "???"
```

This is more code, but it's also more explicit.

To explain how `case_when()` works, let's explore some simpler cases. If none of the cases match, the output gets an NA :

```
case_when(  
  x < 0 ~ "-ve",  
  x > 0 ~ "+ve")  
#> [1] "-ve" "-ve" "-ve" NA    "+ve" "+ve" "+ve" NA
```

If you want to create a “default”/catch all value, use `TRUE` on the left hand side:

```
case_when(  
  x < 0 ~ "-ve",  
  x > 0 ~ "+ve",  
  TRUE ~ "Default")  
#> [1] "-ve" "+ve" "Default"
```

```
TRUE ~ "???"  
}  
#> [1] "-ve" "-ve" "-ve" "???" "+ve" "+ve" "+ve" "???"
```

And note that if multiple conditions match, only the first will be used:

```
case_when(  
  x > 0 ~ "+ve",  
  x > 3 ~ "big"  
)  
#> [1] NA     NA     NA     NA     "+ve" "+ve" "+ve" NA
```

Just like with `if_else()` you can use variables on both sides of the `~` and you can mix and match variables as needed for your problem. For example, we could use `case_when()` to provide some human readable labels for the arrival delay:

```
flights |>  
  mutate(  
    status = case_when(  
      is.na(arr_delay) ~ "cancelled",  
      arr_delay < -30 ~ "very early",  
      arr_delay < -15 ~ "early",  
      abs(arr_delay) <= 15 ~ "on time",  
      arr_delay > 15 ~ "late",  
      arr_delay > 60 ~ "very late",  
    ),  
    .keep = "used"  
)  
#> # A tibble: 336,776 × 2  
#>   arr_delay   status  
#>       <dbl> <chr>  
#> 1        11 on time  
#> 2        20 late  
#> 3        33 late  
#> 4       -18 early
```

```
#> 5      -25 early
#> 6      12 on time
#> # ... with 336,770 more rows
```

14.5.3 Compatible types

Note that both `if_else()` and `case_when()` require **compatible** types in the output. If they're not compatible, you'll see errors like this:

```
if_else(TRUE, "a", 1)
#> Error in `if_else()`:
#> ! Can't combine `true` <character> and `false` <double>

case_when(
  x < -1 ~ TRUE,
  x > 0 ~ lubridate::now()
)
#> Error in `case_when()`:
#> ! Can't combine `TRUE` <logical> and `lubridate::now`
```

Overall, relatively few types are compatible, because automatically converting one type of vector to another is a common source of errors. Here are the most important cases that are compatible:

- Numeric and logical vectors are compatible, as we discussed in [Section 14.4.2](#).
- Strings and factors ([Chapter 18](#)) are compatible, because you can think of a factor as a string with a restricted set of values.
- Dates and date-times, which we'll discuss in [Chapter 19](#), are compatible because you can think of a date as a special case of date-time.
- `NA`, which is technically a logical vector, is compatible with everything because every vector has some way of representing a

missing value.

We don't expect you to memorize these rules, but they should become second nature over time because they are applied consistently throughout the tidyverse.

14.6 Summary

The definition of a logical vector is simple because each value must be either TRUE , FALSE , or NA . But logical vectors provide a huge amount of power. In this chapter, you learned how to create logical vectors with `>`, `<`, `<=`, `=>`, `==`, `!=`, and `is.na()`, how to combine them with `!`, `&`, and `|`, and how to summarize them with `any()`, `all()`, `sum()`, and `mean()`. You also learned the powerful `if_else()` and `case_when()` functions that allow you to return values depending on the value of a logical vector.

We'll see logical vectors again and again in the following chapters. For example in [Chapter 16](#) you'll learn about `str_detect(x, pattern)` which returns a logical vector that's TRUE for the elements of `x` that match the `pattern`, and in [Chapter 19](#) you'll create logical vectors from the comparison of dates and times. But for now, we're going to move onto the next most important type of vector: numeric vectors.

1. R normally calls `print` for you (i.e. `x` is a shortcut for `print(x)`), but calling it explicitly is useful if you want to provide other arguments.
2. That is, `xor(x, y)` is true if `x` is true, or `y` is true, but not both. This is how we usually use "or" in English. "Both" is not usually an acceptable answer to the question "would you like ice cream or cake?".

3. We'll cover this in [Chapter 21](#) 

4. dplyr's `if_else()` is very similar to base R's `ifelse()`. There are two main advantages of `if_else()` over `ifelse()`: you can choose what should happen to missing values, and `if_else()` is much more likely to give you a meaningful error if your variables have incompatible types. 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

15.1 Introduction

Numeric vectors are the backbone of data science, and you've already used them a bunch of times earlier in the book. Now it's time to systematically survey what you can do with them in R, ensuring that you're well situated to tackle any future problem involving numeric vectors.

We'll start by giving you a couple of tools to make numbers if you have strings, and then going into a little more detail of `count()`. Then we'll dive into various numeric transformations that pair well with `mutate()`, including more general transformations that can be applied to other types of vector, but are often used with numeric vectors. We'll finish off by covering the summary functions that pair well with `summarize()` and show you how they can also be used with `mutate()`.

15.1.1 Prerequisites

 This chapter relies on features only found in dplyr 1.1.0, which is still in development. If you want to live on the edge, you can get the dev versions with `devtools::install_github("tidyverse/dplyr")`.

This chapter mostly uses functions from base R, which are available without loading any packages. But we still need the tidyverse because we'll use these base R functions inside of tidyverse functions like `mutate()` and `filter()`. Like in the last chapter, we'll use real examples from `nycflights13`, as well as toy examples made with `c()` and `tribble()`.

```
library(tidyverse)
library(nycflights13)
```

15.2 Making numbers

In most cases, you'll get numbers already recorded in one of R's numeric types: integer or double. In some cases, however, you'll encounter them as strings, possibly because you've created them by pivoting from column headers or because something has gone wrong in your data import process.

`readr` provides two useful functions for parsing strings into numbers: `parse_double()` and `parse_number()`. Use `parse_double()` when you have numbers that have been written as strings:

```
x <- c("1.2", "5.6", "1e3")
parse_double(x)
#> [1]    1.2    5.6 1000.0
```

Use `parse_number()` when the string contains non-numeric text that you want to ignore. This is particularly useful for currency data and percentages:

```
x <- c("$1,234", "USD 3,513", "59%")
parse_number(x)
```

```
#> [1] 1234 3513   59
```

15.3 Counts

It's surprising how much data science you can do with just counts and a little basic arithmetic, so dplyr strives to make counting as easy as possible with `count()`. This function is great for quick exploration and checks during analysis:

```
flights |> count(dest)
#> # A tibble: 105 × 2
#>   dest      n
#>   <chr> <int>
#> 1 ABQ      254
#> 2 ACK      265
#> 3 ALB      439
#> 4 ANC       8
#> 5 ATL     17215
#> 6 AUS     2439
#> # ... with 99 more rows
```

(Despite the advice in [Chapter 7](#), we usually put `count()` on a single line because it's usually used at the console for a quick check that a calculation is working as expected.)

If you want to see the most common values, add `sort = TRUE`:

```
flights |> count(dest, sort = TRUE)
#> # A tibble: 105 × 2
#>   dest      n
#>   <chr> <int>
#> 1 ORD     17283
#> 2 ATL     17215
#> 3 LAX     16174
```

```
#> 4 BOS 15508  
#> 5 MCO 14082  
#> 6 CLT 14064  
#> # ... with 99 more rows
```

And remember that if you want to see all the values, you can use `|> View()` or `|> print(n = Inf)`.

You can perform the same computation “by hand” with `group_by()`, `summarize()` and `n()`. This is useful because it allows you to compute other summaries at the same time:

```
flights |>  
  group_by(dest) |>  
  summarize(  
    n = n(),  
    delay = mean(arr_delay, na.rm = TRUE)  
)  
#> # A tibble: 105 × 3  
#>   dest      n  delay  
#>   <chr> <int> <dbl>  
#> 1 ABQ      254  4.38  
#> 2 ACK      265  4.85  
#> 3 ALB      439 14.4  
#> 4 ANC       8 -2.5  
#> 5 ATL     17215 11.3  
#> 6 AUS     2439  6.02  
#> # ... with 99 more rows
```

`n()` is a special summary function that doesn’t take any arguments and instead accesses information about the “current” group. This means that it only works inside dplyr verbs:

```
n()  
#> Error in `n()`:
```

```
#> ! Must only be used inside data-masking verbs like `n`  
#>   `filter()`, and `group_by()`.
```

There are a couple of variants of `n()` that you might find useful:

- `n_distinct(x)` counts the number of distinct (unique) values of one or more variables. For example, we could figure out which destinations are served by the most carriers:

```
flights |>  
  group_by(dest) |>  
  summarize(  
    carriers = n_distinct(carrier)  
  ) |>  
  arrange(desc(carriers))  
#> # A tibble: 105 × 2  
#>   dest   carriers  
#>   <chr>     <int>  
#> 1 ATL         7  
#> 2 BOS         7  
#> 3 CLT         7  
#> 4 ORD         7  
#> 5 TPA         7  
#> 6 AUS         6  
#> # ... with 99 more rows
```

- A weighted count is a sum. For example you could “count” the number of miles each plane flew:

```
flights |>  
  group_by(tailnum) |>  
  summarize(miles = sum(distance))  
#> # A tibble: 4,044 × 2  
#>   tailnum   miles  
#>   <chr>     <dbl>
```

```
#> 1 D942DN    3418
#> 2 N0EGMQ   250866
#> 3 N10156   115966
#> 4 N102UW    25722
#> 5 N103US    24619
#> 6 N104UW    25157
#> # ... with 4,038 more rows
```

Weighted counts are a common problem so `count()` has a `wt` argument that does the same thing:

```
flights |> count(tailnum, wt = distance)
#> # A tibble: 4,044 × 2
#>   tailnum      n
#>   <chr>     <dbl>
#> 1 D942DN     3418
#> 2 N0EGMQ   250866
#> 3 N10156   115966
#> 4 N102UW    25722
#> 5 N103US    24619
#> 6 N104UW    25157
#> # ... with 4,038 more rows
```

- You can count missing values by combining `sum()` and `is.na()`. In the `flights` dataset this represents flights that are cancelled:

```
flights |>
  group_by(dest) |>
  summarize(n_cancelled = sum(is.na(dep_time)))
#> # A tibble: 105 × 2
#>   dest  n_cancelled
#>   <chr>     <int>
#> 1 ABQ        0
#> 2 ACK        0
#> 3 ALB       20
#> 4 ANC        0
#> 5 ATL      317
```

```
#> 6 AUS          21  
#> # ... with 99 more rows
```

15.3.1 Exercises

1. How can you use `count()` to count the number rows with a missing value for a given variable?
2. Expand the following calls to `count()` to instead use `group_by()`, `summarize()`, and `arrange()`:
 1. `flights |> count(dest, sort = TRUE)`
 2. `flights |> count(tailnum, wt = distance)`

15.4 Numeric transformations

Transformation functions work well with `mutate()` because their output is the same length as the input. The vast majority of transformation functions are already built into base R. It's impractical to list them all so this section will show the most useful ones. As an example, while R provides all the trigonometric functions that you might dream of, we don't list them here because they're rarely needed for data science.

15.4.1 Arithmetic and recycling rules

We introduced the basics of arithmetic (`+`, `-`, `*`, `/`, `^`) in [Chapter 3](#) and have used them a bunch since. These functions don't need a huge amount of explanation because they do what you learned in grade school. But we need to briefly talk about the **recycling rules** which determine what happens when the left and right hand sides have different lengths. This is important for operations like `flights |> mutate(air_time = air_time / 60)` because there are 336,776 numbers on the left of `/` but only one on the right.

R handles mismatched lengths by **recycling**, or repeating, the short vector. We can see this in operation more easily if we create some vectors outside of a data frame:

```
x <- c(1, 2, 10, 20)
x / 5
#> [1] 0.2 0.4 2.0 4.0
# is shorthand for
x / c(5, 5, 5, 5)
#> [1] 0.2 0.4 2.0 4.0
```

Generally, you only want to recycle single numbers (i.e. vectors of length 1), but R will recycle any shorter length vector. It usually (but not always) gives you a warning if the longer vector isn't a multiple of the shorter:

```
x * c(1, 2)
#> [1] 1 4 10 40
x * c(1, 2, 3)
#> Warning in x * c(1, 2, 3): longer object length is no
#> object length
#> [1] 1 4 30 20
```

These recycling rules are also applied to logical comparisons (`==`, `<`, `<=`, `>`, `>=`, `!=`) and can lead to a surprising result if you accidentally use `==` instead of `%in%` and the data frame has an unfortunate number of rows. For example, take this code which attempts to find all flights in January and February:

```
flights |>
  filter(month == c(1, 2))
#> # A tibble: 25,977 × 19
#>   year month   day dep_time sched_dep_time dep_delay arr_time arr_delay
#>   <int> <int> <int> <int> <int> <dbl> <int>
```

```
#> 1 2013 1 1 517 515 2 836
#> 2 2013 1 1 542 540 2 923
#> 3 2013 1 1 554 600 -6 812
#> 4 2013 1 1 555 600 -5 913
#> 5 2013 1 1 557 600 -3 838
#> 6 2013 1 1 558 600 -2 849
#> # ... with 25,971 more rows, 9 more variables: flight <
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, and abbreviated v
#> #   ^sched_dep_time, ^dep_delay, ^arr_time, ^sched_ar
```

The code runs without error, but it doesn't return what you want.

Because of the recycling rules it finds flights in odd numbered rows that departed in January and flights in even numbered rows that departed in February. And unfortunately there's no warning because `flights` has an even number of rows.

To protect you from this type of silent failure, most tidyverse functions use a stricter form of recycling that only recycles single values. Unfortunately that doesn't help here, or in many other cases, because the key computation is performed by the base R function `==`, not `filter()`.

15.4.2 Minimum and maximum

The arithmetic functions work with pairs of variables. Two closely related functions are `pmin()` and `pmax()`, which when given two or more variables will return the smallest or largest value in each row:

```
df <- tribble(
  ~x, ~y,
  1, 3,
  5, 2,
  7, NA,
```

```
)  
  
df |>  
  mutate(  
    min = pmin(x, y, na.rm = TRUE),  
    max = pmax(x, y, na.rm = TRUE)  
  )  
#> # A tibble: 3 × 4  
#>   x     y     min     max  
#>   <dbl> <dbl> <dbl> <dbl>  
#> 1     1     3     1     3  
#> 2     5     2     2     5  
#> 3     7     NA    7     7
```

Note that these are different to the summary functions `min()` and `max()` which take multiple observations and return a single value. You can tell that you've used the wrong form when all the minimums and all the maximums have the same value:

```
df |>  
  mutate(  
    min = min(x, y, na.rm = TRUE),  
    max = max(x, y, na.rm = TRUE)  
  )  
#> # A tibble: 3 × 4  
#>   x     y     min     max  
#>   <dbl> <dbl> <dbl> <dbl>  
#> 1     1     3     1     7  
#> 2     5     2     1     7  
#> 3     7     NA    1     7
```

15.4.3 Modular arithmetic

Modular arithmetic is the technical name for the type of math you did before you learned about real numbers, i.e. division that yields a whole

number and a remainder. In R, `%/%` does integer division and `%%` computes the remainder:

```
1:10 %% 3  
#> [1] 0 0 1 1 1 2 2 2 3 3  
1:10 %% 3  
#> [1] 1 2 0 1 2 0 1 2 0 1
```

Modular arithmetic is handy for the flights dataset, because we can use it to unpack the `sched_dep_time` variable into `hour` and `minute`:

```
flights |>  
  mutate(  
    hour = sched_dep_time %/% 100,  
    minute = sched_dep_time %% 100,  
    .keep = "used"  
)  
#> # A tibble: 336,776 × 3  
#>   sched_dep_time   hour   minute  
#>       <dbl>     <dbl>     <dbl>  
#> 1      515       5       15  
#> 2      529       5       29  
#> 3      540       5       40  
#> 4      545       5       45  
#> 5      600       6        0  
#> 6      558       5       58  
#> # ... with 336,770 more rows
```

We can combine that with the `mean(is.na(x))` trick from [Section 14.4](#) to see how the proportion of cancelled flights varies over the course of the day. The results are shown in [Figure 15.1](#).

```
flights |>  
  group_by(hour = sched_dep_time %/% 100) |>  
  summarize(prop_cancelled = mean(is.na(dep_time)), n =
```

```
filter(hour > 1) |>
ggplot(aes(x = hour, y = prop_cancelled)) +
geom_line(color = "grey50") +
geom_point(aes(size = n))
```

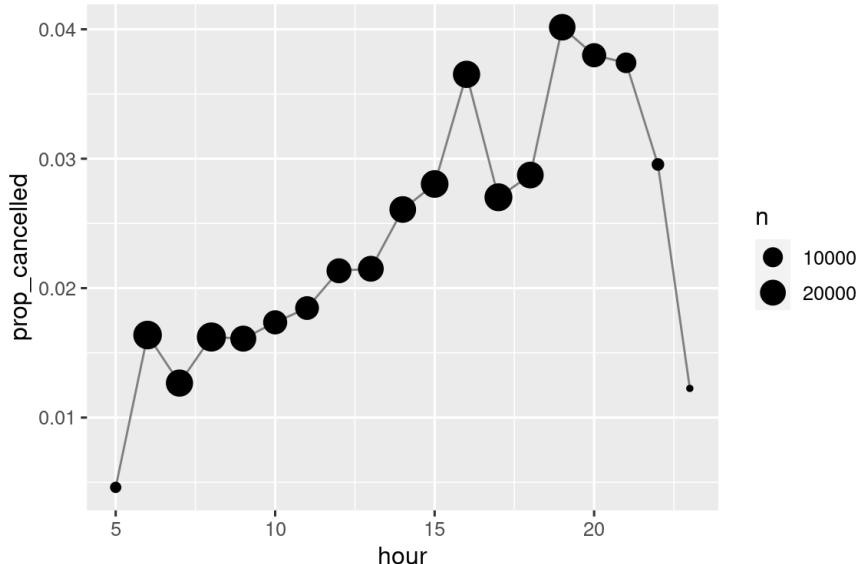

Figure 15.1: A line plot with scheduled departure hour on the x-axis, and proportion of cancelled flights on the y-axis. Cancellations seem to accumulate over the course of the day until 8pm, very late flights are much less likely to be cancelled.

15.4.4 Logarithms

Logarithms are an incredibly useful transformation for dealing with data that ranges across multiple orders of magnitude. They also convert exponential growth to linear growth. For example, take compounding interest — the amount of money you have at `year + 1` is the amount

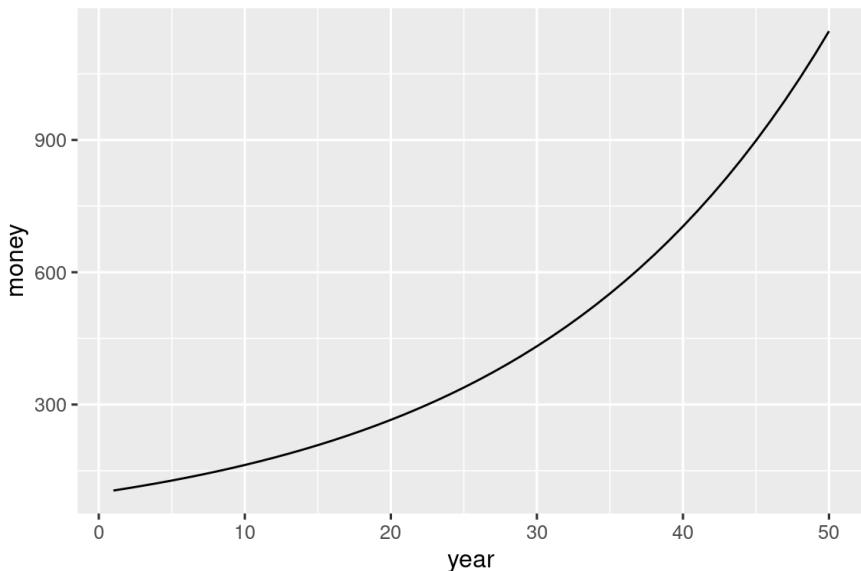

of money you had at year multiplied by the interest rate. That gives a formula like `money = starting * interest ^ year`:

```
starting <- 100
interest <- 1.05

money <- tibble(
  year = 1:50,
  money = starting * interest ^ year
)
```

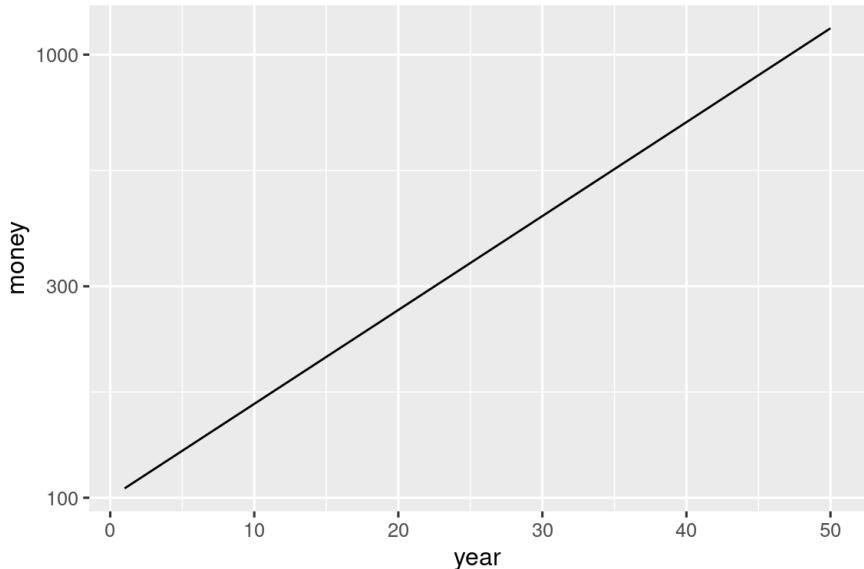

If you plot this data, you'll get an exponential curve showing how your money grows year by year at an interest rate of 1.05:

```
ggplot(money, aes(x = year, y = money)) +
  geom_line()
```

Log transforming the y-axis gives a straight line:

```
ggplot(money, aes(x = year, y = money)) +  
  geom_line() +  
  scale_y_log10()
```

This is a straight line because a little algebra reveals that `log10(money) = log10(interest) * year + log10(starting)`, which matches the pattern for a line, $y = m * x + b$. This is a useful pattern: if you see a (roughly) straight line after log-transforming the y-axis, you know that there's underlying exponential growth.

If you're log-transforming your data with dplyr you have a choice of three logarithms provided by base R: `log()` (the natural log, base e), `log2()` (base 2), and `log10()` (base 10). We recommend using `log2()` or `log10()`. `log2()` is easy to interpret because a difference of 1 on the log scale corresponds to doubling on the original scale and a difference of -1 corresponds to halving; whereas `log10()` is easy to back-transform because (e.g.) 3 is $10^3 = 1000$.

The inverse of `log()` is `exp()`; to compute the inverse of `log2()` or `log10()` you'll need to use `2^` or `10^`.

15.4.5 Rounding

Use `round(x)` to round a number to the nearest integer:

```
round(123.456)
#> [1] 123
```

You can control the precision of the rounding with the second argument, `digits`. `round(x, digits)` rounds to the nearest 10^{-n} so `digits = 2` will round to the nearest 0.01. This definition is useful because it implies `round(x, -3)` will round to the nearest thousand, which indeed it does:

```
round(123.456, 2) # two digits
#> [1] 123.46
round(123.456, 1) # one digit
#> [1] 123.5
round(123.456, -1) # round to nearest ten
#> [1] 120
round(123.456, -2) # round to nearest hundred
#> [1] 100
```

There's one weirdness with `round()` that seems surprising at first glance:

```
round(c(1.5, 2.5))
#> [1] 2 2
```

`round()` uses what's known as "round half to even" or Banker's rounding: if a number is half way between two integers, it will be rounded to the **even** integer. This is a good strategy because it keeps the

rounding unbiased: half of all 0.5s are rounded up, and half are rounded down.

`round()` is paired with `floor()` which always rounds down and `ceiling()` which always rounds up:

```
x <- 123.456
```

```
floor(x)
#> [1] 123
ceiling(x)
#> [1] 124
```

These functions don't have a `digits` argument, so you can instead scale down, round, and then scale back up:

```
# Round down to nearest two digits
floor(x / 0.01) * 0.01
#> [1] 123.45
# Round up to nearest two digits
ceiling(x / 0.01) * 0.01
#> [1] 123.46
```

You can use the same technique if you want to `round()` to a multiple of some other number:

```
# Round to nearest multiple of 4
round(x / 4) * 4
#> [1] 124

# Round to nearest 0.25
round(x / 0.25) * 0.25
#> [1] 123.5
```

15.4.6 Cutting numbers into ranges

Use `cut()`¹ to break up a numeric vector into discrete buckets:

```
x <- c(1, 2, 5, 10, 15, 20)
cut(x, breaks = c(0, 5, 10, 15, 20))
#> [1] (0,5]   (0,5]   (0,5]   (5,10]  (10,15] (15,20]
#> Levels: (0,5] (5,10] (10,15] (15,20]
```

The breaks don't need to be evenly spaced:

```
cut(x, breaks = c(0, 5, 10, 100))
#> [1] (0,5]   (0,5]   (0,5]   (5,10]  (10,100] (10,
#> Levels: (0,5] (5,10] (10,100]
```

You can optionally supply your own `labels`. Note that there should be one less `labels` than `breaks`.

```
cut(x,
  breaks = c(0, 5, 10, 15, 20),
  labels = c("sm", "md", "lg", "xl")
)
#> [1] sm sm sm md lg xl
#> Levels: sm md lg xl
```

Any values outside of the range of the breaks will become `NA`:

```
y <- c(NA, -10, 5, 10, 30)
cut(y, breaks = c(0, 5, 10, 15, 20))
#> [1] <NA>   <NA>   (0,5]   (5,10] <NA>
#> Levels: (0,5] (5,10] (10,15] (15,20]
```

See the documentation for other useful arguments like `right` and `include.lowest`, which control if the intervals are `[a, b]` or `(a, b]` and if the lowest interval should be `[a, b]`.

15.4.7 Cumulative and rolling aggregates

Base R provides `cumsum()`, `cumprod()`, `cummin()`, `cummax()` for running, or cumulative, sums, products, mins and maxes. dplyr provides `cummean()` for cumulative means. Cumulative sums tend to come up the most in practice:

```
x <- 1:10
cumsum(x)
#> [1] 1 3 6 10 15 21 28 36 45 55
```

If you need more complex rolling or sliding aggregates, try the [slider](#) package by Davis Vaughan. The following example illustrates some of its features.

```
library(slider)

# Same as a cumulative sum
slide_vec(x, sum, .before = Inf)
#> [1] 1 3 6 10 15 21 28 36 45 55
# Sum the current element and the one before it
slide_vec(x, sum, .before = 1)
#> [1] 1 3 5 7 9 11 13 15 17 19
# Sum the current element and the two before and after it
slide_vec(x, sum, .before = 2, .after = 2)
#> [1] 6 10 15 20 25 30 35 40 34 27
# Only compute if the window is complete
slide_vec(x, sum, .before = 2, .after = 2, .complete = T)
#> [1] NA NA 15 20 25 30 35 40 NA NA
```

15.4.8 Exercises

1. Explain in words what each line of the code used to generate [Figure 15.1](#) does.
2. What trigonometric functions does R provide? Guess some names and look up the documentation. Do they use degrees or radians?
3. Currently `dep_time` and `sched_dep_time` are convenient to look at, but hard to compute with because they're not really continuous numbers. You can see the basic problem in this plot: there's a gap between each hour.

```
flights |>
  filter(month == 1, day == 1) |>
  ggplot(aes(x = sched_dep_time, y = dep_delay)) +
  geom_point()  
#> Warning: Removed 4 rows containing missing values
```

Convert them to a more truthful representation of time (either fractional hours or minutes since midnight).

15.5 General transformations

The following sections describe some general transformations which are often used with numeric vectors, but can be applied to all other column types.

15.5.1 Ranks

dplyr provides a number of ranking functions inspired by SQL, but you should always start with `dplyr::min_rank()`. It uses the typical method for dealing with ties, e.g. 1st, 2nd, 2nd, 4th.

```
x <- c(1, 2, 2, 3, 4, NA)
min_rank(x)
#> [1] 1 2 2 4 5 NA
```

Note that the smallest values get the lowest ranks; use `desc(x)` to give the largest values the smallest ranks:

```
min_rank(desc(x))
#> [1] 5 3 3 2 1 NA
```

If `min_rank()` doesn't do what you need, look at the variants `dplyr::row_number()`, `dplyr::dense_rank()`, `dplyr::percent_rank()`, and `dplyr::cume_dist()`. See the documentation for details.

```
df <- tibble(x = x)
df |>
  mutate(
    row_number = row_number(x),
    dense_rank = dense_rank(x),
    percent_rank = percent_rank(x),
    cume_dist = cume_dist(x)
  )
#> # A tibble: 6 × 5
#>       x  row_number  dense_rank  percent_rank  cume_dist
#>   <dbl>      <int>      <int>        <dbl>      <dbl>
#> 1     1          1          1         0           0.2
#> 2     2          2          2         0.25        0.6
#> 3     2          3          2         0.25        0.6
#> 4     3          4          3         0.75        0.8
```

```
#> 5      4      5      4      1      1  
#> 6    NA     NA     NA    NA    NA
```

You can achieve many of the same results by picking the appropriate `ties.method` argument to base R's `rank()`; you'll probably also want to set `na.last = "keep"` to keep NAs as NA.

`row_number()` can also be used without any arguments when inside a dplyr verb. In this case, it'll give the number of the “current” row. When combined with `%%` or `%/%` this can be a useful tool for dividing data into similarly sized groups:

```
df <- tibble(x = runif(10))  
  
df |>  
  mutate(  
    row0 = row_number() - 1,  
    three_groups = row0 %% 3,  
    three_in_each_group = row0 %/% 3,  
  )  
#> # A tibble: 10 × 4  
#>       x   row0 three_groups three_in_each_group  
#>   <dbl> <dbl>        <dbl>                 <dbl>  
#> 1 0.0808     0          0                  0  
#> 2 0.834      1          1                  0  
#> 3 0.601      2          2                  0  
#> 4 0.157      3          0                  1  
#> 5 0.00740    4          1                  1  
#> 6 0.466      5          2                  1  
#> # ... with 4 more rows
```

15.5.2 Offsets

`dplyr::lead()` and `dplyr::lag()` allow you to refer the values just before or just after the “current” value. They return a vector of the same length as the input, padded with NAs at the start or end:

```
x <- c(2, 5, 11, 11, 19, 35)
lag(x)
#> [1] NA  2  5 11 11 19
lead(x)
#> [1]  5 11 11 19 35 NA
```

- `x - lag(x)` gives you the difference between the current and previous value.

```
x - lag(x)
#> [1] NA  3  6  0  8 16
```

- `x == lag(x)` tells you when the current value changes.

```
x == lag(x)
#> [1]      NA FALSE FALSE  TRUE FALSE FALSE
```

You can lead or lag by more than one position by using the second argument, `n`.

15.5.3 Consecutive identifiers

Sometimes you want to start a new group every time some event occurs. For example, when you’re looking at website data, it’s common to want to break up events into sessions, where a session is defined as a gap of more than x minutes since the last activity.

For example, imagine you have the times when someone visited a website:

```
events <- tibble(
  time = c(0, 1, 2, 3, 5, 10, 12, 15, 17, 19, 20, 27, 28
```

```
)
```

And you've the time lag between the events, and figured out if there's a gap that's big enough to qualify:

```
events <- events |>
  mutate(
    diff = time - lag(time, default = first(time)),
    gap = diff >= 5
  )
events
#> # A tibble: 14 × 3
#>   time   diff   gap
#>   <dbl> <dbl> <lgl>
#> 1     0     0 FALSE
#> 2     1     1 FALSE
#> 3     2     1 FALSE
#> 4     3     1 FALSE
#> 5     5     2 FALSE
#> 6    10     5 TRUE
#> # ... with 8 more rows
```

But how do we go from that logical vector to something that we can `group_by()`? `cumsum()` from [Section 15.4.7](#) comes to the rescue as each occurring gap, i.e., `gap` is `TRUE`, increments `group` by one (see [Section 14.4.2](#) on the numerical interpretation of logicals):

```
events |> mutate(
  group = cumsum(gap)
)
#> # A tibble: 14 × 4
#>   time   diff   gap   group
#>   <dbl> <dbl> <lgl> <int>
#> 1     0     0 FALSE      0
#> 2     1     1 FALSE      0
```

```
#> 3      2      1 FALSE    0
#> 4      3      1 FALSE    0
#> 5      5      2 FALSE    0
#> 6     10      5 TRUE     1
#> # ... with 8 more rows
```

Another approach for creating grouping variables is

`consecutive_id()`, which starts a new group every time one of its arguments changes. For example, inspired by [this stackoverflow question](#), imagine you have a data frame with a bunch of repeated values:

```
df <- tibble(
  x = c("a", "a", "a", "b", "c", "c", "d", "e", "a", "a",
        1, 2, 3, 2, 4, 1, 3, 9, 4, 8, 10, 199)
)
df
#> # A tibble: 12 × 2
#>   x       y
#>   <chr> <dbl>
#> 1 a       1
#> 2 a       2
#> 3 a       3
#> 4 b       2
#> 5 c       4
#> 6 c       1
#> # ... with 6 more rows
```

You want to keep the first row from each repeated `x`. That's easier to express with a combination of `consecutive_id()` and `slice_head()`:

```
df |>
  group_by(id = consecutive_id(x)) |>
```

```
slice_head(n = 1)
#> # A tibble: 7 × 3
#> # Groups:   id [7]
#>   x       y     id
#>   <chr> <dbl> <int>
#> 1 a         1     1
#> 2 b         2     2
#> 3 c         4     3
#> 4 d         3     4
#> 5 e         9     5
#> 6 a         4     6
#> # ... with 1 more row
```

15.5.4 Exercises

1. Find the 10 most delayed flights using a ranking function. How do you want to handle ties? Carefully read the documentation for `min_rank()`.
2. Which plane (`tailnum`) has the worst on-time record?
3. What time of day should you fly if you want to avoid delays as much as possible?
4. What does `flights |> group_by(dest) |> filter(row_number() < 4)` do? What does `flights |> group_by(dest) |> filter(row_number(dep_delay) < 4)` do?
5. For each destination, compute the total minutes of delay. For each flight, compute the proportion of the total delay for its destination.
6. Delays are typically temporally correlated: even once the problem that caused the initial delay has been resolved, later flights are delayed to allow earlier flights to leave. Using `lag()`, explore how

the average flight delay for an hour is related to the average delay for the previous hour.

```
flights |>
  mutate(hour = dep_time %/% 100) |>
  group_by(year, month, day, hour) |>
  summarize(
    dep_delay = mean(dep_delay, na.rm = TRUE),
    n = n(),
    .groups = "drop"
  ) |>
  filter(n > 5)
```

7. Look at each destination. Can you find flights that are suspiciously fast (i.e. flights that represent a potential data entry error)? Compute the air time of a flight relative to the shortest flight to that destination. Which flights were most delayed in the air?
8. Find all destinations that are flown by at least two carriers. Use those destinations to come up with a relative ranking of the carriers based on their performance for the same destination.

15.6 Numeric summaries

Just using the counts, means, and sums that we've introduced already can get you a long way, but R provides many other useful summary functions. Here is a selection that you might find useful.

15.6.1 Center

So far, we've mostly used `mean()` to summarize the center of a vector of values. Because the mean is the sum divided by the count, it is sensitive to even just a few unusually high or low values. An alternative is to use the `median()`, which finds a value that lies in the “middle” of the

vector, i.e. 50% of the values is above it and 50% are below it. Depending on the shape of the distribution of the variable you're interested in, mean or median might be a better measure of center. For example, for symmetric distributions we generally report the mean while for skewed distributions we usually report the median.

[Figure 15.2](#) compares the mean vs. the median when looking at the hourly vs. median departure delay. The median delay is always smaller than the mean delay because flights sometimes leave multiple hours late, but never leave multiple hours early.

```
flights |>
  group_by(year, month, day) |>
  summarize(
    mean = mean(dep_delay, na.rm = TRUE),
    median = median(dep_delay, na.rm = TRUE),
    n = n(),
    .groups = "drop"
  ) |>
  ggplot(aes(x = mean, y = median)) +
  geom_abline(slope = 1, intercept = 0, color = "white",
  geom_point()
#> Warning: Using `size` aesthetic for lines was deprecated
#> i Please use `linewidth` instead.
```

 All points fall below a 45° line, meaning that the median delay is always less than the mean delay. Most points are clustered in a dense region of mean [0, 20] and median [0, 5]. As the mean delay increases, the spread of the median also increases. There are two outlying points with mean ~60, median ~50, and mean ~85, median ~55.

Figure 15.2: A scatterplot showing the differences of summarising hourly departure delay with median instead of mean.

You might also wonder about the **mode**, or the most common value. This is a summary that only works well for very simple cases (which is why you might have learned about it in high school), but it doesn't work well for many real datasets. If the data is discrete, there may be multiple most common values, and if the data is continuous, there might be no most common value because every value is ever so slightly different. For these reasons, the mode tends not to be used by statisticians and there's no mode function included in base R².

15.6.2 Minimum, maximum, and quantiles

What if you're interested in locations other than the center? `min()` and `max()` will give you the largest and smallest values. Another powerful tool is `quantile()` which is a generalization of the median:

`quantile(x, 0.25)` will find the value of `x` that is greater than 25% of the values, `quantile(x, 0.5)` is equivalent to the median, and `quantile(x, 0.95)` will find the value that's greater than 95% of the values.

For the `flights` data, you might want to look at the 95% quantile of delays rather than the maximum, because it will ignore the 5% of most delayed flights which can be quite extreme.

```
flights |>
  group_by(year, month, day) |>
  summarize(
    max = max(dep_delay, na.rm = TRUE),
    q95 = quantile(dep_delay, 0.95, na.rm = TRUE),
    .groups = "drop"
  )
#> # A tibble: 365 × 5
#>   year  month   day   max   q95
#>   <int> <int> <int> <dbl> <dbl>
#> 1  2013     1     1    853  70.1
```

```
#> 2 2013     1     2   379   85
#> 3 2013     1     3   291   68
#> 4 2013     1     4   288   60
#> 5 2013     1     5   327   41
#> 6 2013     1     6   202   51
#> # ... with 359 more rows
```

15.6.3 Spread

Sometimes you're not so interested in where the bulk of the data lies, but in how it is spread out. Two commonly used summaries are the standard deviation, `sd(x)`, and the inter-quartile range, `IQR()`. We won't explain `sd()` here since you're probably already familiar with it, but `IQR()` might be new — it's `quantile(x, 0.75) - quantile(x, 0.25)` and gives you the range that contains the middle 50% of the data.

We can use this to reveal a small oddity in the `flights` data. You might expect the spread of the distance between origin and destination to be zero, since airports are always in the same place. But the code below makes it look like one airport, `EGE`, might have moved.

```
flights |>
  group_by(origin, dest) |>
  summarize(
    distance_sd = IQR(distance),
    n = n(),
    .groups = "drop"
  ) |>
  filter(distance_sd > 0)
#> # A tibble: 2 × 4
#>   origin dest  distance_sd     n
#>   <chr>   <chr>      <dbl> <int>
#> 1 EWR     EGE        110     1
#> 2 JFK     EGE        103     1
```

15.6.4 Distributions

It's worth remembering that all of the summary statistics described above are a way of reducing the distribution down to a single number. This means that they're fundamentally reductive, and if you pick the wrong summary, you can easily miss important differences between groups. That's why it's always a good idea to visualize the distribution before committing to your summary statistics.

Figure 15.3 shows the overall distribution of departure delays. The distribution is so skewed that we have to zoom in to see the bulk of the data. This suggests that the mean is unlikely to be a good summary and we might prefer the median instead.

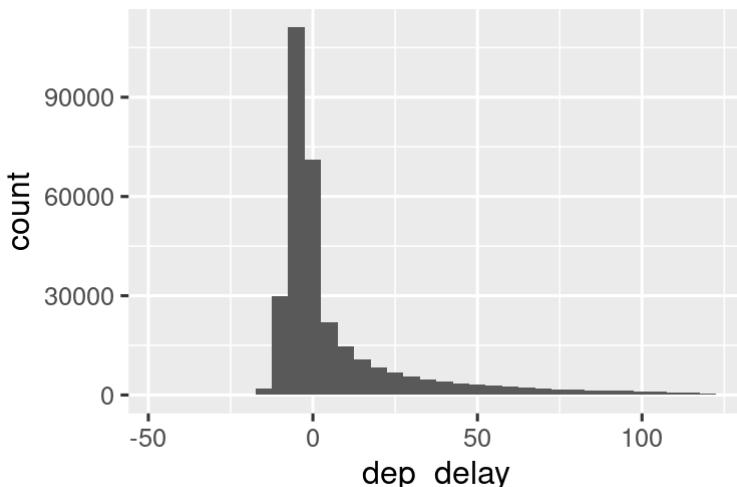

```
flights |>
  ggplot(aes(x = dep_delay)) +
  geom_histogram(binwidth = 15)
#> Warning: Removed 8255 rows containing non-finite values
```

```
flights |>
  filter(dep_delay < 120) |>
  ggplot(aes(x = dep_delay)) +
  geom_histogram(binwidth = 5)
```

 Two histograms of `dep_delay` . On the left, it's very hard to see any pattern except that there's a very large spike around zero, the bars rapidly decay in height, and for most of the plot, you can't see any bars because they are too short to see. On the right, where we've discarded delays of greater than two hours, we can see that the spike occurs slightly below zero (i.e. most flights leave a couple of minutes early), but there's still a very steep decay after that.

(a) Histogram shows the full range of delays.

(b) Histogram is zoomed in to show delays less than 2 hours.

Figure 15.3: The distribution of `dep_delay` appears highly skewed to the right in both histograms.

It's also a good idea to check that distributions for subgroups resemble the whole. [Figure 15.4](#) overlays a frequency polygon for each day. The distributions seem to follow a common pattern, suggesting it's fine to use the same summary for each day.

```
flights |>  
  filter(dep_delay < 120) |>
```

```
ggplot(aes(x = dep_delay, group = interaction(day, mon)) +  
  geom_freqpoly(binwidth = 5, alpha = 1/5)
```

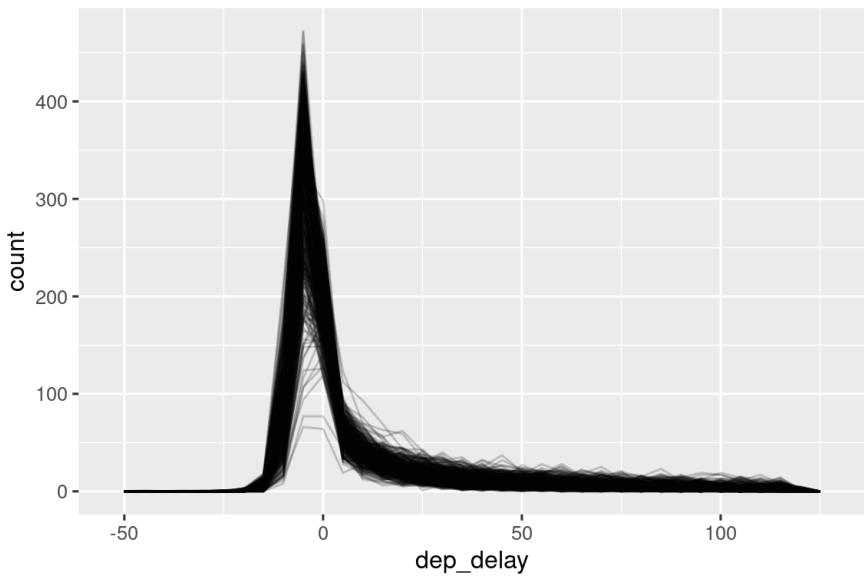

Figure 15.4: 365 frequency polygons of `dep_delay`, one for each day. The frequency polygons appear to have the same shape, suggesting that it's reasonable to compare days by looking at just a few summary statistics.

Don't be afraid to explore your own custom summaries specifically tailored for the data that you're working with. In this case, that might mean separately summarizing the flights that left early vs. the flights that left late, or given that the values are so heavily skewed, you might try a log-transformation. Finally, don't forget what you learned in [Section 4.5](#): whenever creating numerical summaries, it's a good idea to include the number of observations in each group.

15.6.5 Positions

There's one final type of summary that's useful for numeric vectors, but also works with every other type of value: extracting a value at a specific position. You can do this with the base R `[` function, but we're not going to cover it in detail until [Section 29.1](#), because it's a very powerful and general function. For now we'll introduce three specialized functions that you can use to extract values at a specified position: `first(x)`, `last(x)`, and `nth(x, n)`.

For example, we can find the first and last departure for each day:

```
flights |>
  group_by(year, month, day) |>
  summarise(
    first_dep = first(dep_time),
    fifth_dep = nth(dep_time, 5),
    last_dep = last(dep_time)
  )
#> `summarise()` has grouped output by 'year', 'month'.
#> the `groups` argument.
#> # A tibble: 365 × 6
#> # Groups:   year, month [12]
#>   year month   day first_dep fifth_dep last_dep
#>   <int> <int> <int>     <int>     <int>    <int>
#> 1  2013     1     1       517      554      NA
#> 2  2013     1     2       42       535      NA
#> 3  2013     1     3       32       520      NA
#> 4  2013     1     4       25       531      NA
#> 5  2013     1     5       14       534      NA
#> 6  2013     1     6       16       555      NA
#> # ... with 359 more rows
```

(These functions currently lack an `na.rm` argument but will hopefully be fixed by the time you read this book:
<https://github.com/tidyverse/dplyr/issues/6242>).

If you're familiar with `[`, you might wonder if you ever need these functions. There are two main reasons: the `default` argument and the `order_by` argument. `default` allows you to set a default value that's used if the requested position doesn't exist, e.g. you're trying to get the 3rd element from a two element group. `order_by` lets you locally override the existing ordering of the rows, so you can get the element at the position in the ordering by `order_by()`.

Extracting values at positions is complementary to filtering on ranks. Filtering gives you all variables, with each observation in a separate row:

```
flights |>
  group_by(year, month, day) |>
  mutate(r = min_rank(desc(sched_dep_time))) |>
  filter(r %in% c(1, max(r)))
#> # A tibble: 1,195 × 20
#> # Groups:   year, month, day [365]
#>   year month   day dep_time sched_dep_time1 dep_delay2 arr_time3
#>   <int> <int> <int>     <int>      <int>     <dbl>     <int>
#> 1 2013     1     1      517        515       2     830
#> 2 2013     1     1     2353       2359      -6     425
#> 3 2013     1     1     2353       2359      -6     418
#> 4 2013     1     1     2356       2359      -3     425
#> 5 2013     1     2      42        2359      43     518
#> 6 2013     1     2     458        500      -2     703
#> # ... with 1,189 more rows, 10 more variables: flight <
#> #   origin <chr>, dest <chr>, air_time <dbl>, distance
#> #   minute <dbl>, time_hour <dttm>, r <int>, and abbr
#> #   1sched_dep_time, 2dep_delay, 3arr_time, 4sched_ar
```

15.6.6 With `mutate()`

As the names suggest, the summary functions are typically paired with `summarize()`. However, because of the recycling rules we discussed in [Section 15.4.1](#) they can also be usefully paired with `mutate()`, particularly when you want do some sort of group standardization. For example:

- `x / sum(x)` calculates the proportion of a total.
- `(x - mean(x)) / sd(x)` computes a Z-score (standardized to mean 0 and sd 1).
- `x / first(x)` computes an index based on the first observation.

15.6.7 Exercises

1. Brainstorm at least 5 different ways to assess the typical delay characteristics of a group of flights. Consider the following scenarios:

- A flight is 15 minutes early 50% of the time, and 15 minutes late 50% of the time.
- A flight is always 10 minutes late.
- A flight is 30 minutes early 50% of the time, and 30 minutes late 50% of the time.
- 99% of the time a flight is on time. 1% of the time it's 2 hours late.

Which do you think is more important: arrival delay or departure delay?

2. Which destinations show the greatest variation in air speed?

3. Create a plot to further explore the adventures of EGE. Can you find any evidence that the airport moved locations?

15.7 Summary

You're already familiar with many tools for working with numbers, and after reading this chapter you now know how to use them in R. You've also learned a handful of useful general transformations that are commonly, but not exclusively, applied to numeric vectors like ranks and offsets. Finally, you worked through a number of numeric summaries, and discussed a few of the statistical challenges that you should consider.

Over the next two chapters, we'll dive into working with strings with the `stringr` package. Strings are a big topic so they get two chapters, one on the fundamentals of strings and one on regular expressions.

1. `ggplot2` provides some helpers for common cases in `cut_interval()`, `cut_number()`, and `cut_width()`. `ggplot2` is an admittedly weird place for these functions to live, but they are useful as part of histogram computation and were written before any other parts of the tidyverse existed. 
2. The `mode()` function does something quite different! 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

16.1 Introduction

So far, you've used a bunch of strings without learning much about the details. Now it's time to dive into them, learn what makes strings tick, and master some of the powerful string manipulation tools you have at your disposal.

We'll begin with the details of creating strings and character vectors. You'll then dive into creating strings from data, then the opposite; extracting strings from data. We'll then discuss tools that work with individual letters. The chapter finishes with functions that work with individual letters and a brief discussion of where your expectations from English might steer you wrong when working with other languages.

We'll keep working with strings in the next chapter, where you'll learn more about the power of regular expressions.

16.1.1 Prerequisites

 This chapter relies on features only found in `tidyverse` 1.3.0, which is still in development. If you want to live on the edge, you can get the dev versions with `devtools::install_github("tidyverse/tidyr")`.

In this chapter, we'll use functions from the `stringr` package, which is part of the core tidyverse. We'll also use the `babynames` data since it provides some fun strings to manipulate.

```
library(tidyverse)
library(babynames)
```

You can quickly tell when you're using a `stringr` function because all `stringr` functions start with `str_`. This is particularly useful if you use RStudio because typing `str_` will trigger autocomplete, allowing you to jog your memory of the available functions.

```
> str_c          {stringr}  str_c(..., sep = "", collapse = NULL)
> str_conv       {stringr}
> str_count      {stringr}
> str_detect     {stringr}
> str_dup        {stringr}
> str_extract    {stringr}
> str_extract_all {stringr}
> str_|
```

To understand how `str_c` works, you need to imagine that you are building up a matrix of strings. Each input argument forms a column, and is expanded to the length of the longest argument, using the usual recycling rules. The `sep` string is inserted between each column. If `collapse` is `NULL` each row is collapsed into a single string. If non-`NULL` that string is inserted at the end of each row, and the entire matrix collapsed to a single string.

Press F1 for additional help

16.2 Creating a string

We've created strings in passing earlier in the book but didn't discuss the details. Firstly, you can create a string using either single quotes (`'`) or double quotes (`"`). There's no difference in behavior between the two, so in the interests of consistency, the [tidyverse style guide](#) recommends using `"`, unless the string contains multiple `"`.

```
string1 <- "This is a string"
string2 <- 'If I want to include a "quote" inside a stri
```

If you forget to close a quote, you'll see `+`, the continuation character:

```
> "This is a string without a closing quote  
+  
+  
+ HELP I'M STUCK IN A STRING
```

If this happens to you and you can't figure out which quote to close, press Escape to cancel and try again.

16.2.1 Escapes

To include a literal single or double quote in a string, you can use `\` to “escape” it:

```
double_quote <- "\\"" # or '\"'  
single_quote <- '\\"' # or "'"
```

So if you want to include a literal backslash in your string, you'll need to escape it: `"\\\"`:

```
backslash <- "\\\"
```

Beware that the printed representation of a string is not the same as the string itself because the printed representation shows the escapes (in other words, when you print a string, you can copy and paste the output to recreate that string). To see the raw contents of the string, use `str_view()`¹:

```
x <- c(single_quote, double_quote, backslash)  
x  
#> [1] "" "|\\" "\\""  
  
str_view(x)  
#> [1] | '
```

```
#> [2] | "
#> [3] | \
```

16.2.2 Raw strings

Creating a string with multiple quotes or backslashes gets confusing quickly. To illustrate the problem, let's create a string that contains the contents of the code block where we define the `double_quote` and `single_quote` variables:

```
tricky <- "double_quote <- \"\\\"\\\"\\\" # or '\"'
single_quote <- '\\\'' # or \"'\\\""
str_view(tricky)
#> [1] | double_quote <- "\\"# or """
#>     | single_quote <- '\'# or """
```

That's a lot of backslashes! (This is sometimes called [leaning toothpick syndrome](#).) To eliminate the escaping, you can instead use a **raw string**²:

```
tricky <- r"(double_quote <- \"\"# or """
single_quote <- '\\\'# or """)"
str_view(tricky)
#> [1] | double_quote <- "\\"# or """
#>     | single_quote <- '\'# or """
```

A raw string usually starts with `r"("` and finishes with `")"`. But if your string contains `")"` you can instead use `r"[]"` or `r"{}"`, and if that's still not enough, you can insert any number of dashes to make the opening and closing pairs unique, e.g., ``r"--()--"`, ``r"---()---"`, etc. Raw strings are flexible enough to handle any text.

16.2.3 Other special characters

As well as `\"`, `\'`, and `\\"`, there are a handful of other special characters that may come in handy. The most common are `\n`, newline, and `\t`, tab. You'll also sometimes see strings containing Unicode escapes that start with `\u` or `\U`. This is a way of writing non-English characters that work on all systems. You can see the complete list of other special characters in [?!!!](#).

```
x <- c("one\ntwo", "one\ttwo", "\u00b5", "\u0001f604")
x
#> [1] "one\ntwo"  "one\ttwo"  "\u00b5"      "😊"
str_view(x)
#> [1] | one
#> [2] | two
#> [3] | one{\|t}two
#> [4] | \u00b5
#> [5] | 😊
```

Note that `str_view()` uses a blue background for tabs to make them easier to spot. One of the challenges of working with text is that there's a variety of ways that white space can end up in the text, so this background helps you recognize that something strange is going on.

16.2.4 Exercises

1. Create strings that contain the following values:

1. He said "That's amazing!"

2. `\a\b\c\d`

3. `\|||||`

2. Create the string in your R session and print it. What happens to the special “`\u00a0`”? How does `str_view()` display it? Can you do a little googling to figure out what this special character is?

```
x <- "This\u00a0is\u00a0tricky"
```

16.3 Creating many strings from data

Now that you've learned the basics of creating a string or two by "hand", we'll go into the details of creating strings from other strings. This will help you solve the common problem where you have some text you wrote that you want to combine with strings from a data frame. For example, you might combine "Hello" with a `name` variable to create a greeting. We'll show you how to do this with `str_c()` and `str_glue()` and how you can use them with `mutate()`. That naturally raises the question of what string functions you might use with `summarize()`, so we'll finish this section with a discussion of `str_flatten()`, which is a summary function for strings.

16.3.1 `str_c()`

`str_c()` takes any number of vectors as arguments and returns a character vector:

```
str_c("x", "y")
#> [1] "xy"
str_c("x", "y", "z")
#> [1] "xyz"
str_c("Hello ", c("John", "Susan"))
#> [1] "Hello John"  "Hello Susan"
```

`str_c()` is very similar to the base `paste0()`, but is designed to be used with `mutate()` by obeying the usual tidyverse rules for recycling and propagating missing values:

```
set.seed(1410)
df <- tibble(name = c(wakefield::name(3), NA))
df |> mutate(greeting = str_c("Hi ", name, "!="))
#> # A tibble: 4 × 2
#>   name      greeting
#>   <chr>    <chr>
#> 1 Ilena     Hi Ilena!
#> 2 Sacramento Hi Sacramento!
#> 3 Graylon   Hi Graylon!
#> 4 <NA>      <NA>
```

If you want missing values to display in another way, use `coalesce()` to replace them. Depending on what you want, you might use it either inside or outside of `str_c()`:

```
df |>
  mutate(
    greeting1 = str_c("Hi ", coalesce(name, "you"), "!="),
    greeting2 = coalesce(str_c("Hi ", name, "!="), "Hi!")
  )
#> # A tibble: 4 × 3
#>   name      greeting1     greeting2
#>   <chr>    <chr>        <chr>
#> 1 Ilena     Hi Ilena!   Hi Ilena!
#> 2 Sacramento Hi Sacramento! Hi Sacramento!
#> 3 Graylon   Hi Graylon! Hi Graylon!
#> 4 <NA>      Hi you!     Hi!
```

16.3.2 `str_glue()`

If you are mixing many fixed and variable strings with `str_c()`, you'll notice that you type a lot of `"`s, making it hard to see the overall goal of the code. An alternative approach is provided by the [glue package](#) via

`str_glue()`³. You give it a single string that has a special feature: anything inside `{}` will be evaluated like it's outside of the quotes:

```
df |> mutate(greeting = str_glue("Hi {name}!"))
#> # A tibble: 4 × 2
#>   name      greeting
#>   <chr>     <glue>
#> 1 Ilena     Hi Ilena!
#> 2 Sacramento Hi Sacramento!
#> 3 Graylon   Hi Graylon!
#> 4 <NA>      Hi NA!
```

As you can see, `str_glue()` currently converts missing values to the string "NA" unfortunately making it inconsistent with `str_c()`.

You also might wonder what happens if you need to include a regular `{` or `}` in your string. You're on the right track if you guess you'll need to escape it somehow. The trick is that glue uses a slightly different escaping technique; instead of prefixing with special character like `\`, you double up the special characters:

```
df |> mutate(greeting = str_glue("{{Hi {name}!}}"))
#> # A tibble: 4 × 2
#>   name      greeting
#>   <chr>     <glue>
#> 1 Ilena     {Hi Ilena!}
#> 2 Sacramento {Hi Sacramento!}
#> 3 Graylon   {Hi Graylon!}
#> 4 <NA>      {Hi NA!}
```

16.3.3 `str_flatten()`

`str_c()` and `glue()` work well with `mutate()` because their output is the same length as their inputs. What if you want a function that works well with `summarize()`, i.e., something that always returns a

single string? That's the job of `str_flatten()`⁴: it takes a character vector and combines each element of the vector into a single string:

```
str_flatten(c("x", "y", "z"))
#> [1] "xyz"
str_flatten(c("x", "y", "z"), ", ")
#> [1] "x, y, z"
str_flatten(c("x", "y", "z"), ", ", last = ", and ")
#> [1] "x, y, and z"
```

This makes it work well with `summarize()`:

```
df <- tribble(
  ~ name, ~ fruit,
  "Carmen", "banana",
  "Carmen", "apple",
  "Marvin", "nectarine",
  "Terence", "cantaloupe",
  "Terence", "papaya",
  "Terence", "madarine"
)
df |>
  group_by(name) |>
  summarize(fruits = str_flatten(fruit, ", "))

#> # A tibble: 3 × 2
#>   name    fruits
#>   <chr>   <chr>
#> 1 Carmen  banana, apple
#> 2 Marvin  nectarine
#> 3 Terence cantaloupe, papaya, madarine
```

16.3.4 Exercises

1. Compare and contrast the results of `paste0()` with `str_c()` for the following inputs:

```
str_c("hi ", NA)
str_c(letters[1:2], letters[1:3])
```

2. Convert the following expressions from `str_c()` to `str_glue()` or vice versa:

- a. `str_c("The price of ", food, " is ", price)`
- b. `str_glue("I'm {age} years old and live in {country}")`
- c. `str_c("\section{", title, "}")`

16.4 Extracting data from strings

It's very common for multiple variables to be crammed together into a single string. In this section, you'll learn how to use four `tidyverse` functions to extract them:

- `df |> separate_longer_delim(col, delim)`
- `df |> separate_longer_position(col, width)`
- `df |> separate_wider_delim(col, delim, names)`
- `df |> separate_wider_position(col, widths)`

If you look closely, you can see there's a common pattern here: `separate_`, then `longer` or `wider`, then `_`, then by `delim` or `position`. That's because these four functions are composed of two simpler primitives:

- `longer` makes the input data frame longer, creating new rows; `wider` makes the input data frame wider, generating new columns.
- `delim` splits up a string with a delimiter like `", "` or `" "`; `position` splits at specified widths, like `c(3, 5, 2)`.

We'll return to the last member of this family, `separate_regex_wider()`, in [Chapter 17](#). It's the most flexible of the `wider` functions, but you need to know something about regular expressions before you can use it.

The following two sections will give you the basic idea behind these `separate` functions, first separating into rows (which is a little simpler) and then separating into columns. We'll finish off by discussing the tools that the `wider` functions give you to diagnose problems.

16.4.1 Separating into rows

Separating a string into rows tends to be most useful when the number of components varies from row to row. The most common case is requiring `separate_longer_delim()` to split based on a delimiter:

```
df1 <- tibble(x = c("a,b,c", "d,e", "f"))
df1 |>
  separate_longer_delim(x, delim = ",")
#> # A tibble: 6 × 1
#>   x
#>   <chr>
#> 1 a
#> 2 b
#> 3 c
#> 4 d
#> 5 e
#> 6 f
```

It's rarer to see `separate_longer_position()` in the wild, but some older datasets do use a very compact format where each character is used to record a value:

```
df2 <- tibble(x = c("1211", "131", "21"))
df2 |>
```

```
separate_longer_position(x, width = 1)
#> # A tibble: 9 × 1
#>   x
#>   <chr>
#> 1 1
#> 2 2
#> 3 1
#> 4 1
#> 5 1
#> 6 3
#> # ... with 3 more rows
```

16.4.2 Separating into columns

Separating a string into columns tends to be most useful when there are a fixed number of components in each string, and you want to spread them into columns. They are slightly more complicated than their longer equivalents because you need to name the columns. For example, in this following dataset, `x` is made up of a code, an edition number, and a year, separated by `"."`. To use `separate_wider_delim()`, we supply the delimiter and the names in two arguments:

```
df3 <- tibble(x = c("a10.1.2022", "b10.2.2011", "e15.1.2")
df3 |>
  separate_wider_delim(
    x,
    delim = ".",
    names = c("code", "edition", "year")
  )
#> # A tibble: 3 × 3
#>   code  edition year
#>   <chr> <chr>   <chr>
#> 1 a10    1      2022
```

```
#> 2 b10    2      2011  
#> 3 e15    1      2015
```

If a specific piece is not useful you can use an NA name to omit it from the results:

```
df3 |>  
  separate_wider_delim(  
    x,  
    delim = ".",
    names = c("code", NA, "year")
  )  
#> # A tibble: 3 × 2  
#>   code    year  
#>   <chr> <chr>  
#> 1 a10    2022  
#> 2 b10    2011  
#> 3 e15    2015
```

`separate_wider_position()` works a little differently because you typically want to specify the width of each column. So you give it a named integer vector, where the name gives the name of the new column, and the value is the number of characters it occupies. You can omit values from the output by not naming them:

```
df4 <- tibble(x = c("202215TX", "202122LA", "202325CA"))  
df4 |>  
  separate_wider_position(  
    x,  
    widths = c(year = 4, age = 2, state = 2)
  )  
#> # A tibble: 3 × 3  
#>   year  age  state  
#>   <chr> <chr> <chr>
```

```
#> 1 2022 15 TX  
#> 2 2021 22 LA  
#> 3 2023 25 CA
```

16.4.3 Diagnosing widening problems

`separate_wider_delim()`⁵ requires a fixed and known set of columns. What happens if some of the rows don't have the expected number of pieces? There are two possible problems, too few or too many pieces, so `separate_wider_delim()` provides two arguments to help: `too_few` and `too_many`. Let's first look at the `too_few` case with the following sample dataset:

```
df <- tibble(x = c("1-1-1", "1-1-2", "1-3", "1-3-2", "1-  
  
df |>  
  separate_wider_delim(  
    x,  
    delim = "-",
    names = c("x", "y", "z")
  )  
#> Error in `separate_wider_delim()`:  
#> ! Expected 3 pieces in each element of `x`.  
#> ! 2 values were too short.  
#> i Use `too_few = "debug"` to diagnose the problem.  
#> i Use `too_few = "align_start"/"align_end"` to silence
```

You'll notice that we get an error, but the error gives us some suggestions on how you might proceed. Let's start by debugging the problem:

```
debug <- df |>
  separate_wider_delim(
    x,
    delim = "-",
    names = c("x", "y", "z"),
    too_few = "debug"
  )
#> Warning: Debug mode activated: adding variables `x_ok`
#> `x_remainder`.
debug
#> # A tibble: 5 × 6
#>   x     y     z     x_ok x_pieces x_remainder
#>   <chr> <chr> <chr> <lgl>   <int> <chr>
#> 1 1-1-1 1     1     TRUE      3  ""
#> 2 1-1-2 1     2     TRUE      3  ""
#> 3 1-3     3     <NA> FALSE     2  ""
#> 4 1-3-2 3     2     TRUE      3  ""
#> 5 1     <NA> <NA> FALSE     1  ""
```

When you use the debug mode, you get three extra columns added to the output: `x_ok`, `x_pieces`, and `x_remainder` (if you separate a variable with a different name, you'll get a different prefix). Here, `x_ok` lets you quickly find the inputs that failed:

```
debug |> filter(!x_ok)
#> # A tibble: 2 × 6
#>   x     y     z     x_ok x_pieces x_remainder
#>   <chr> <chr> <chr> <lgl>   <int> <chr>
#> 1 1-3     3     <NA> FALSE      2  ""
#> 2 1     <NA> <NA> FALSE      1  ""
```

`x_pieces` tells us how many pieces were found, compared to the expected 3 (the length of `names`). `x_remainder` isn't useful when there

are too few pieces, but we'll see it again shortly.

Sometimes looking at this debugging information will reveal a problem with your delimiter strategy or suggest that you need to do more preprocessing before separating. In that case, fix the problem upstream and make sure to remove `too_few = "debug"` to ensure that new problems become errors.

In other cases, you may want to fill in the missing pieces with `NA`s and move on. That's the job of `too_few = "align_start"` and `too_few = "align_end"` which allow you to control where the `NA`s should go:

```
df |>
  separate_wider_delim(
    x,
    delim = "-",
    names = c("x", "y", "z"),
    too_few = "align_start"
  )
#> # A tibble: 5 × 3
#>   x     y     z
#>   <chr> <chr> <chr>
#> 1 1     1     1
#> 2 1     1     2
#> 3 1     3     <NA>
#> 4 1     3     2
#> 5 1     <NA>  <NA>
```

The same principles apply if you have too many pieces:

```
df <- tibble(x = c("1-1-1", "1-1-2", "1-3-5-6", "1-3-2",
df |>
  separate_wider_delim(
    x,
```

```
    delim = "-",
    names = c("x", "y", "z")
)
#> Error in `separate_wider_delim()`:
#> ! Expected 3 pieces in each element of `x`.
#> ! 2 values were too long.
#> i Use `too_many = "debug"` to diagnose the problem.
#> i Use `too_many = "drop"/"merge"` to silence this mes
```

But now, when we debug the result, you can see the purpose of `x_remainder`:

```
debug <- df |>
  separate_wider_delim(
    x,
    delim = "-",
    names = c("x", "y", "z"),
    too_many = "debug"
)
#> Warning: Debug mode activated: adding variables `x_ok`
#> `x_remainder`.
debug |> filter(!x_ok)
#> # A tibble: 2 × 6
#>   x         y     z     x_ok x_pieces x_remainder
#>   <chr>     <chr> <chr> <lgl>    <int> <chr>
#> 1 1-3-5-6   3     5     FALSE      4 -6
#> 2 1-3-5-7-9 3     5     FALSE      5 -7-9
```

You have a slightly different set of options for handling too many pieces: you can either silently “drop” any additional pieces or “merge” them all into the final column:

```
df |>
  separate_wider_delim(
    x,
    delim = "-",
    names = c("x", "y", "z"),
    too_many = "drop"
  )
#> # A tibble: 5 × 3
#>   x     y     z
#>   <chr> <chr> <chr>
#> 1 1     1     1
#> 2 1     1     2
#> 3 1     3     5
#> 4 1     3     2
#> 5 1     3     5
```

```
df |>
  separate_wider_delim(
    x,
    delim = "-",
    names = c("x", "y", "z"),
    too_many = "merge"
  )
#> # A tibble: 5 × 3
#>   x     y     z
#>   <chr> <chr> <chr>
#> 1 1     1     1
#> 2 1     1     2
#> 3 1     3     5-6
#> 4 1     3     2
#> 5 1     3     5-7-9
```

16.5 Letters

In this section, we'll introduce you to functions that allow you to work with the individual letters within a string. You'll learn how to find the length of a string, extract substrings, and handle long strings in plots and tables.

16.5.1 Length

`str_length()` tells you the number of letters in the string:

```
str_length(c("a", "R for data science", NA))  
#> [1] 1 18 NA
```

You could use this with `count()` to find the distribution of lengths of US babynames and then with `filter()` to look at the longest names⁶:

```
babynames |>  
  count(length = str_length(name), wt = n)  
#> # A tibble: 14 × 2  
#>   length      n  
#>   <int>    <int>  
#> 1      2    338150  
#> 2      3    8589596  
#> 3      4    48506739  
#> 4      5    87011607  
#> 5      6    90749404  
#> 6      7    72120767  
#> # ... with 8 more rows  
  
babynames |>  
  filter(str_length(name) == 15) |>  
  count(name, wt = n, sort = TRUE)  
#> # A tibble: 34 × 2  
#>   name            n  
#>   <chr>          <int>  
#> 1 Franciscojavier 123
```

```
#> 2 Christopherjohn 118  
#> 3 Johnchristopher 118  
#> 4 Christopherjame 108  
#> 5 Christophermich 52  
#> 6 Ryanchristopher 45  
#> # ... with 28 more rows
```

16.5.2 Subsetting

You can extract parts of a string using `str_sub(string, start, end)`, where `start` and `end` are the positions where the substring should start and end. The `start` and `end` arguments are inclusive, so the length of the returned string will be `end - start + 1`:

```
x <- c("Apple", "Banana", "Pear")  
str_sub(x, 1, 3)  
#> [1] "App" "Ban" "Pea"
```

You can use negative values to count back from the end of the string: `-1` is the last character, `-2` is the second to last character, etc.

```
str_sub(x, -3, -1)  
#> [1] "ple" "ana" "ear"
```

Note that `str_sub()` won't fail if the string is too short: it will just return as much as possible:

```
str_sub("a", 1, 5)  
#> [1] "a"
```

We could use `str_sub()` with `mutate()` to find the first and last letter of each name:

```
babynames |>
  mutate(
    first = str_sub(name, 1, 1),
    last = str_sub(name, -1, -1)
  )
#> # A tibble: 1,924,665 × 7
#>   year sex   name      n   prop first last
#>   <dbl> <chr> <chr> <int> <dbl> <chr> <chr>
#> 1 1880 F   Mary     7065 0.0724 M   y
#> 2 1880 F   Anna    2604 0.0267 A   a
#> 3 1880 F   Emma    2003 0.0205 E   a
#> 4 1880 F   Elizabeth 1939 0.0199 E   h
#> 5 1880 F   Minnie   1746 0.0179 M   e
#> 6 1880 F   Margaret 1578 0.0162 M   t
#> # ... with 1,924,659 more rows
```

16.5.3 Long strings

Sometimes you care about the length of a string because you’re trying to fit it into a label on a plot or table. stringr provides two useful tools for cases where your string is too long:

- `str_trunc(x, 30)` ensures that no string is longer than 30 characters, replacing any letters after 30 with `...`.
- `str_wrap(x, 30)` wraps a string introducing new lines so that each line is at most 30 characters (it doesn’t hyphenate, however, so any word longer than 30 characters will make a longer line)

The following code shows these functions in action with a made-up string:

```
x <- "Lorem ipsum dolor sit amet, consectetur adipiscing
```

```
str_view(str_trunc(x, 30))
#> [1] | Lorem ipsum dolor sit amet, ...
str_view(str_wrap(x, 30))
#> [1] | Lorem ipsum dolor sit amet,
#>      consectetur adipiscing
#>      elit, sed do eiusmod tempor
#>      incididunt ut labore et dolore
#>      magna aliqua. Ut enim ad
#>      minim veniam, quis nostrud
#>      exercitation ullamco laboris
#>      nisi ut aliquip ex ea commodo
#>      consequat.
```

16.5.4 Exercises

1. Use `str_length()` and `str_sub()` to extract the middle letter from each baby name. What will you do if the string has an even number of characters?
2. Are there any major trends in the length of babynames over time? What about the popularity of first and last letters?

16.6 Non-English text

So far, we've focused on English language text which is particularly easy to work with for two reasons. Firstly, the English alphabet is relatively simple: there are just 26 letters. Secondly (and maybe more importantly), the computing infrastructure we use today was predominantly designed by English speakers. Unfortunately, we don't have room for a full treatment of non-English languages. Still, we wanted to draw your attention to some of the biggest challenges you might encounter: encoding, letter variations, and locale-dependent functions.

16.6.1 Encoding

When working with non-English text, the first challenge is often the **encoding**. To understand what's going on, we need to dive into how computers represent strings. In R, we can get at the underlying representation of a string using `charToRaw()`:

```
charToRaw("Hadley")
#> [1] 48 61 64 6c 65 79
```

Each of these six hexadecimal numbers represents one letter: 48 is H, 61 is a, and so on. The mapping from hexadecimal number to character is called the encoding, and in this case, the encoding is called ASCII. ASCII does a great job of representing English characters because it's the **American Standard Code for Information Interchange**.

Things aren't so easy for languages other than English. In the early days of computing, there were many competing standards for encoding non-English characters. For example, there were two different encodings for Europe: Latin1 (aka ISO-8859-1) was used for Western European languages, and Latin2 (aka ISO-8859-2) was used for Central European languages. In Latin1, the byte b1 is “±”, but in Latin2, it's “ä”! Fortunately, today there is one standard that is supported almost everywhere: UTF-8. UTF-8 can encode just about every character used by humans today and many extra symbols like emojis.

`readr` uses UTF-8 everywhere. This is a good default but will fail for data produced by older systems that don't use UTF-8. If this happens, your strings will look weird when you print them. Sometimes just one or two characters might be messed up; other times, you'll get complete gibberish. For example here are two inline CSVs with unusual encodings⁷:

```
x1 <- "text\nEl Ni\xf1o was particularly bad this year"
read_csv(x1)
#> # A tibble: 1 × 1
#>   text
#>   <chr>
#> 1 "El Ni\xf1o was particularly bad this year"

x2 <- "text\n\x82\xb1\x82\xf1\x82\xc9\x82\xbf\x82\xcd"
read_csv(x2)
#> # A tibble: 1 × 1
#>   text
#>   <chr>
#> 1 "|x82\xb1\x82\xf1\x82\xc9\x82\xbf\x82\xcd"
```

To read these correctly, you specify the encoding via the `locale` argument:

```
read_csv(x1, locale = locale(encoding = "Latin1"))
#> # A tibble: 1 × 1
#>   text
#>   <chr>
#> 1 El Niño was particularly bad this year

read_csv(x2, locale = locale(encoding = "Shift-JIS"))
#> # A tibble: 1 × 1
#>   text
#>   <chr>
#> 1 こんにちは
```

How do you find the correct encoding? If you're lucky, it'll be included somewhere in the data documentation. Unfortunately, that's rarely the case, so `readr` provides `guess_encoding()` to help you figure it out. It's not foolproof and works better when you have lots of text (unlike here),

but it's a reasonable place to start. Expect to try a few different encodings before you find the right one.

```
guess_encoding(x1)
#> # A tibble: 1 × 2
#>   encoding    confidence
#>   <chr>          <dbl>
#> 1 ISO-8859-1      0.41
guess_encoding(x2)
#> # A tibble: 1 × 2
#>   encoding    confidence
#>   <chr>          <dbl>
#> 1 KOI8-R        0.27
```

Encodings are a rich and complex topic; we've only scratched the surface here. If you'd like to learn more, we recommend reading the detailed explanation at <http://kunststube.net/encoding/>.

16.6.2 Letter variations

Working in languages with accents poses a significant challenge when determining the position of letters (e.g., with `str_length()` and `str_sub()`) as accented letters might be encoded as a single individual character (e.g., ü) or as two characters by combining an unaccented letter (e.g., u) with a diacritic mark (e.g., `). For example, this code shows two ways of representing ü that look identical:

```
u <- c("\u00fc", "u\u0308")
str_view(u)
#> [1] | ü
#> [2] | ü
```

But both strings differ in length, and their first characters are different:

```
str_length(u)
#> [1] 1 2
str_sub(u, 1, 1)
#> [1] "ü" "u"
```

Finally, note that a comparison of these strings with `==` interprets these strings as different, while the handy `str_equal()` function in `stringr` recognizes that both have the same appearance:

```
u[[1]] == u[[2]]
#> [1] FALSE

str_equal(u[[1]], u[[2]])
#> [1] TRUE
```

16.6.3 Locale-dependent functions

Finally, there are a handful of `stringr` functions whose behavior depends on your **locale**. A locale is similar to a language but includes an optional region specifier to handle regional variations within a language. A locale is specified by a lower-case language abbreviation, optionally followed by a `_` and an upper-case region identifier. For example, “en” is English, “en_GB” is British English, and “en_US” is American English. If you don’t already know the code for your language, [Wikipedia](#) has a good list, and you can see which are supported in `stringr` by looking at `stringi::stri_locale_list()`.

Base R string functions automatically use the locale set by your operating system. This means that base R string functions do what you expect for your language, but your code might work differently if you share it with someone who lives in a different country. To avoid this problem, `stringr` defaults to English rules by using the “en” locale and requires you to specify the `locale` argument to override it. Fortunately,

there are two sets of functions where the locale really matters: changing case and sorting.

The rules for changing cases differ among languages. For example, Turkish has two i's: with and without a dot. Since they're two distinct letters, they're capitalized differently:

```
str_to_upper(c("i", "ı"))
#> [1] "I" "I"
str_to_upper(c("i", "ı"), locale = "tr")
#> [1] "İ" "I"
```

Sorting strings depends on the order of the alphabet, and the order of the alphabet is not the same in every language⁸! Here's an example: in Czech, "ch" is a compound letter that appears after h in the alphabet.

```
str_sort(c("a", "c", "ch", "h", "z"))
#> [1] "a"   "c"   "ch"  "h"   "z"
str_sort(c("a", "c", "ch", "h", "z"), locale = "cs")
#> [1] "a"   "c"   "h"   "ch"  "z"
```

This also comes up when sorting strings with `dplyr::arrange()`, which is why it also has a `locale` argument.

16.7 Summary

In this chapter, you've learned about some of the power of the stringr package: how to create, combine, and extract strings, and about some of the challenges you might face with non-English strings. Now it's time to learn one of the most important and powerful tools for working with strings: regular expressions. Regular expressions are a very concise but very expressive language for describing patterns within strings and are the topic of the next chapter.

-
1. Or use the base R function `writeLines()`. 
 2. Available in R 4.0.0 and above. 
 3. If you're not using stringr, you can also access it directly with `glue::glue()`. 
 4. The base R equivalent is `paste()` used with the `collapse` argument. 
 5. The same principles apply to `separate_wider_position()` and `separate_wider_regex()`. 
 6. Looking at these entries, we'd guess that the babynames data drops spaces or hyphens and truncates after 15 letters. 
 7. Here I'm using the special `\x` to encode binary data directly into a string. 
 8. Sorting in languages that don't have an alphabet, like Chinese, is more complicated still. 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

17.1 Introduction

In [Chapter 16](#), you learned a whole bunch of useful functions for working with strings. This chapter will focus on functions that use **regular expressions**, a concise and powerful language for describing patterns within strings. The term “regular expression” is a bit of a mouthful, so most people abbreviate it to “regex”¹ or “regexp”.

The chapter starts with the basics of regular expressions and the most useful stringr functions for data analysis. We’ll then expand your knowledge of patterns and cover seven important new topics (escaping, anchoring, character classes, shorthand classes, quantifiers, precedence, and grouping). Next, we’ll talk about some of the other types of patterns that stringr functions can work with and the various “flags” that allow you to tweak the operation of regular expressions. We’ll finish with a survey of other places in the tidyverse and base R where you might use regexes.

17.1.1 Prerequisites

 This chapter relies on features only found in tidyverse 1.3.0, which is still in development. If you want to live on the edge, you can get the dev

```
version with devtools::install_github("tidyverse/tidyr").
```

In this chapter, we'll use regular expression functions from stringr and tidyr, both core members of the tidyverse, as well as data from the babynames package.

```
library(tidyverse)  
library(babynames)
```

Through this chapter, we'll use a mix of very simple inline examples so you can get the basic idea, the baby names data, and three character vectors from stringr:

- `fruit` contains the names of 80 fruits.
- `words` contains 980 common English words.
- `sentences` contains 720 short sentences.

17.2 Pattern basics

We'll use `str_view()` to learn how regex patterns work. We used `str_view()` in the last chapter to better understand a string vs. its printed representation, and now we'll use it with its second argument, a regular expression. When this is supplied, `str_view()` will show only the elements of the string vector that match, surrounding each match with `<>`, and, where possible, highlighting the match in blue.

The simplest patterns consist of letters and numbers which match those characters exactly:

```
str_view(fruit, "berry")  
#> [6] | bil<berry>  
#> [7] | black<berry>  
#> [10] | blue<berry>
```

```
#> [11] | boysen<berry>
#> [19] | cloud<berry>
#> [21] | cran<berry>
#> [29] | elder<berry>
#> [32] | goji <berry>
#> [33] | goose<berry>
#> [38] | huckle<berry>
#> ... and 4 more
```

```
str_view(fruit, "BERRY")
```

Letters and numbers match exactly and are called **literal characters**.

Punctuation characters like . , + , * , [,] , ? have special meanings² and are called **meta-characters**. For example, . will match any character³, so "a." will match any string that contains an "a" followed by another character :

```
str_view(c("a", "ab", "ae", "bd", "ea", "eab"), "a.")
```

```
#> [2] | <ab>
#> [3] | <ae>
#> [6] | e<ab>
```

Or we could find all the fruits that contain an "a", followed by three letters, followed by an "e":

```
str_view(fruit, "a...e")
```

```
#> [1] | <apple>
#> [7] | bl<ackbe>rry
#> [48] | mand<arine>
#> [51] | nect<arine>
#> [62] | pine<apple>
#> [64] | pomegr<anate>
#> [70] | r<aspbe>rry
#> [73] | sal<al be>rry
```

Quantifiers control how many times a pattern can match:

- ? makes a pattern optional (i.e., it matches 0 or 1 times)
- + lets a pattern repeat (i.e., it matches at least once)
- * lets a pattern be optional or repeat (i.e., it matches any number of times, including 0).

```
# ab? matches an "a", optionally followed by a "b".
str_view(c("a", "ab", "abb"), "ab?")
#> [1] | <a>
#> [2] | <ab>
#> [3] | <ab>b

# ab+ matches an "a", followed by at least one "b".
str_view(c("a", "ab", "abb"), "ab+")
#> [2] | <ab>
#> [3] | <abb>

# ab* matches an "a", followed by any number of "b"s.
str_view(c("a", "ab", "abb"), "ab*")
#> [1] | <a>
#> [2] | <ab>
#> [3] | <abb>
```

Character classes are defined by [] and let you match a set of characters, e.g. [abcd] matches “a”, “b”, “c”, or “d”. You can also invert the match by starting with ^: [^abcd] matches anything **except** “a”, “b”, “c”, or “d”. We can use this idea to find the words with three vowels or four consonants in a row:

```
str_view(words, "[aeiou][aeiou][aeiou]")
#> [79] | b<eau>ty
#> [565] | obv<iou>s
#> [644] | prev<iou>s
#> [670] | q<ui>t
#> [741] | ser<iou>s
#> [915] | var<iou>s
```

```
str_view(words, "[^aeiou][^aeiou][^aeiou][^aeiou]")
#> [45] | a<pply>
#> [198] | cou<ntry>
#> [424] | indu<stry>
#> [830] | su<pply>
#> [836] | <syst>em
```

You can combine character classes and quantifiers. For example, the following regexp looks for two vowels followed by two or more consonants:

```
str_view(words, "[aeiou][aeiou][^aeiou][^aeiou]+")
#> [6] | acc<ount>
#> [21] | ag<ainst>
#> [31] | alr<eady>
#> [34] | alth<ough>
#> [37] | am<ount>
#> [46] | app<oint>
#> [47] | appr<oach>
#> [52] | ar<ound>
#> [61] | <auth>ority
#> [79] | be<auty>
#> ... and 62 more
```

(We'll learn more elegant ways to express these ideas in [Section 17.4.4](#).)

You can use **alternation**, `|` to pick between one or more alternative patterns. For example, the following patterns look for fruits containing “apple”, “pear”, or “banana”, or a repeated vowel.

```
str_view(fruit, "apple|pear|banana")
#> [1] | <apple>
#> [4] | <banana>
#> [59] | <pear>
#> [62] | pine<apple>
str_view(fruit, "aa|ee|ii|oo|uu")
```

```
#> [9] | bl<oo>d orange
#> [33] | g<oo>seberry
#> [47] | lych<ee>
#> [66] | purple mangost<ee>n
```

Regular expressions are very compact and use a lot of punctuation characters, so they can seem overwhelming and hard to read at first. Don’t worry; you’ll get better with practice, and simple patterns will soon become second nature. Let’s kick off that process by practicing with some useful stringr functions.

17.2.1 Exercises

17.3 Key functions

Now that you’ve got the basics of regular expressions under your belt, let’s use them with some stringr and tidyverse functions. In the following section, you’ll learn how to detect the presence or absence of a match, how to count the number of matches, how to replace a match with fixed text, and how to extract text using a pattern.

17.3.1 Detect matches

`str_detect()` returns a logical vector that is `TRUE` if the pattern matches an element of the character vector and `FALSE` otherwise:

```
str_detect(c("a", "b", "c"), "[aeiou]")
#> [1] TRUE FALSE FALSE
```

Since `str_detect()` returns a logical vector of the same length as the initial vector, it pairs well with `filter()`. For example, this code finds all the most popular names containing a lower-case “x”:

```
babynames |>
  filter(str_detect(name, "x")) |>
  count(name, wt = n, sort = TRUE)
#> # A tibble: 974 × 2
#>   name      n
#>   <chr>    <int>
#> 1 Alexander 665492
#> 2 Alexis    399551
#> 3 Alex       278705
#> 4 Alexandra 232223
#> 5 Max        148787
#> 6 Alexa     123032
#> # ... with 968 more rows
```

We can also use `str_detect()` with `summarize()` by pairing it with `sum()` or `mean()`: `sum(str_detect(x, pattern))` tells you the number of observations that match and `mean(str_detect(x, pattern))` tells you the proportion that match. For example, the following snippet computes and visualizes the proportion of baby names⁴ that contain “x”, broken down by year. It looks like they’ve radically increased in popularity lately!

```
babynames |>
  group_by(year) |>
  summarize(prop_x = mean(str_detect(name, "x"))) |>
  ggplot(aes(x = year, y = prop_x)) +
  geom_line()
```

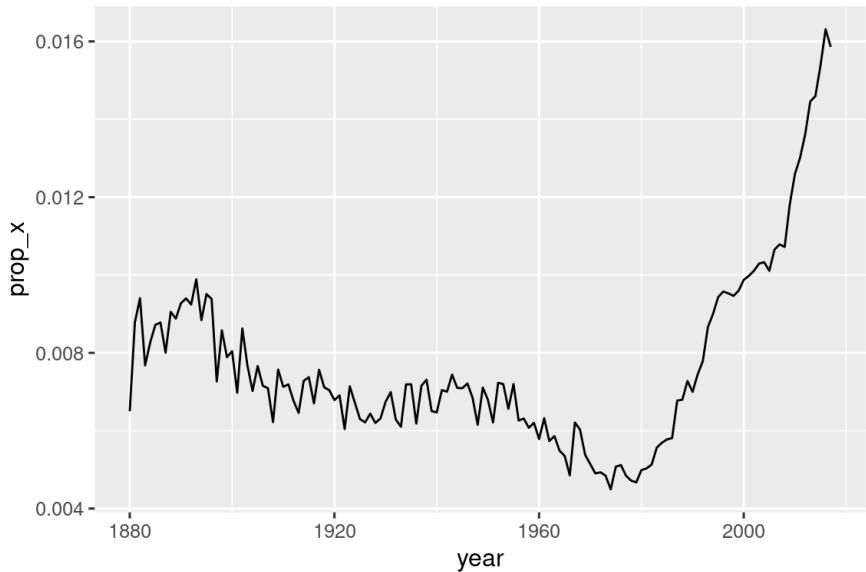

Figure 17.1: A time series showing the proportion of baby names that contain a lower case “x”.

There are two functions that are closely related to `str_detect()`, namely `str_subset()` which returns just the strings that contain a match and `str_which()` which returns the indexes of strings that have a match:

```
str_subset(c("a", "b", "c"), "[aeiou]")
#> [1] "a"
str_which(c("a", "b", "c"), "[aeiou]")
#> [1] 1
```

17.3.2 Count matches

The next step up in complexity from `str_detect()` is `str_count()`: rather than a simple true or false, it tells you how many matches there are in each string.

```
x <- c("apple", "banana", "pear")
str_count(x, "p")
#> [1] 2 0 1
```

Note that each match starts at the end of the previous match; i.e. regex matches never overlap. For example, in "abababa", how many times will the pattern "aba" match? Regular expressions say two, not three:

```
str_count("abababa", "aba")
#> [1] 2
str_view("abababa", "aba")
#> [1] | <aba>b<aba>
```

It's natural to use `str_count()` with `mutate()`. The following example uses `str_count()` with character classes to count the number of vowels and consonants in each name.

```
babynames |>
  count(name) |>
  mutate(
    vowels = str_count(name, "[aeiou]"),
    consonants = str_count(name, "[^aeiou]")
  )
#> # A tibble: 97,310 × 4
#>   name          n vowels consonants
#>   <chr>      <int>  <int>      <int>
#> 1 Aaban        10     2         3
#> 2 Aabha        5      2         3
#> 3 Aabid        2      2         3
#> 4 Aabir        1      2         3
#> 5 Aabriella    5      4         5
#> 6 Aada         1      2         2
#> # ... with 97,304 more rows
```

If you look closely, you'll notice that there's something off with our calculations: "Aaban" contains three "a"s, but our summary reports only two vowels. That's because regular expressions are case sensitive. There are three ways we could fix this:

- Add the upper case vowels to the character class:
`str_count(name, "[aeiouAEIOU]").`
- Tell the regular expression to ignore case:
`str_count(regex(name, ignore_case = TRUE), "[aeiou]").` We'll talk about more in [Section 17.5.1](#).
- Use `str_to_lower()` to convert the names to lower case:
`str_count(str_to_lower(name), "[aeiou]).`

This variety of approaches is pretty typical when working with strings — there are often multiple ways to reach your goal, either by making your pattern more complicated or by doing some preprocessing on your string. If you get stuck trying one approach, it can often be useful to switch gears and tackle the problem from a different perspective.

In this case, since we're applying two functions to the name, I think it's easier to transform it first:

```
babynames |>
  count(name) |>
  mutate(
    name = str_to_lower(name),
    vowels = str_count(name, "[aeiou]"),
    consonants = str_count(name, "[^aeiou]")
  )
#> # A tibble: 97,310 × 4
#>   name           n vowels consonants
#>   <chr>       <int>   <int>      <int>
#> 1 aaban         10      3          2
#> 2 aabha         5       3          2
#> 3 aabid         2       3          2
```

```
#> 4 aabir      1      3      2
#> 5 aabriella  5      5      4
#> 6 aada       1      3      1
#> # ... with 97,304 more rows
```

17.3.3 Replace values

As well as detecting and counting matches, we can also modify them with `str_replace()` and `str_replace_all()`. `str_replace()` replaces the first match, and as the name suggests, `str_replace_all()` replaces all matches.

```
x <- c("apple", "pear", "banana")
str_replace_all(x, "[aeiou]", "-")
#> [1] "-ppl-"   "p--r"    "b-n-n-"
```

`str_remove()` and `str_remove_all()` are handy shortcuts for `str_replace(x, pattern, "")`.

```
x <- c("apple", "pear", "banana")
str_remove_all(x, "[aeiou]")
#> [1] "ppl" "pr"   "bnn"
```

These functions are naturally paired with `mutate()` when doing data cleaning, and you'll often apply them repeatedly to peel off layers of inconsistent formatting.

17.3.4 Extract variables

The last function we'll discuss uses regular expressions to extract data out of one column into one or more new columns:

`separate_wider_regex()`. It's a peer of the `separate_wider_location()` and `separate_wider_delim()` functions that you learned about in [Section 16.4.2](#). These functions live

in `tidyverse` because it operates on (columns of) data frames, rather than individual vectors.

Let's create a simple dataset to show how it works. Here we have some data derived from `babynames` where we have the name, gender, and age of a bunch of people in a rather weird format⁵:

```
df <- tribble(  
  ~str,  
  "<Sheryl>-F_34",  
  "<Kisha>-F_45",  
  "<Brandon>-N_33",  
  "<Sharon>-F_38",  
  "<Penny>-F_58",  
  "<Justin>-M_41",  
  "<Patricia>-F_84",  
)
```

To extract this data using `separate_wider_regex()` we just need to construct a sequence of regular expressions that match each piece. If we want the contents of that piece to appear in the output, we give it a name:

```
df |>  
  separate_wider_regex(  
    str,  
    patterns = c(  
      "<", name = "[A-Za-z]+", ">-",  
      gender = ".", "_",  
      age = "[0-9]+"  
    )  
  )  
#> # A tibble: 7 × 3  
#>   name     gender age  
#>   <chr>    <chr>  <chr>
```

```
#> 1 Sheryl F      34
#> 2 Kisha   F     45
#> 3 Brandon N    33
#> 4 Sharon   F    38
#> 5 Penny    F    58
#> 6 Justin   M    41
#> # ... with 1 more row
```

If the match fails, you can use `too_short = "debug"` to figure out what went wrong, just like `separate_wider_delim()` and `separate_wider_position()`.

17.3.5 Exercises

1. What baby name has the most vowels? What name has the highest proportion of vowels? (Hint: what is the denominator?)
2. Replace all forward slashes in a string with backslashes.
3. Implement a simple version of `str_to_lower()` using `str_replace_all()`.
4. Create a regular expression that will match telephone numbers as commonly written in your country.

17.4 Pattern details

Now that you understand the basics of the pattern language and how to use it with some `stringr` and `tidy` functions, its time to dig into more of the details. First, we'll start with **escaping**, which allows you to match metacharacters that would otherwise be treated specially. Next, you'll learn about **anchors** which allow you to match the start or end of the string. Then, you'll more learn about **character classes** and their shortcuts which allow you to match any character from a set. Next,

you'll learn the final details of **quantifiers** which control how many times a pattern can match. Then, we have to cover the important (but complex) topic of **operator precedence** and parentheses. And we'll finish off with some details of **grouping** components of the pattern.

The terms we use here are the technical names for each component. They're not always the most evocative of their purpose, but it's very helpful to know the correct terms if you later want to Google for more details.

17.4.1 Escaping

In order to match a literal `.`, you need an **escape** which tells the regular expression to match metacharacters literally. Like strings, regexps use the backslash for escaping. So, to match a `.`, you need the regexp `\.`. Unfortunately this creates a problem. We use strings to represent regular expressions, and `\` is also used as an escape symbol in strings. So to create the regular expression `\.` we need the string `"\\.".`, as the following example shows.

```
# To create the regular expression \., we need to use \\.
dot <- "\\.".

# But the expression itself only contains one \
str_view(dot)
#> [1] | \.

# And this tells R to look for an explicit .
str_view(c("abc", "a.c", "bef"), "a\\\.c")
#> [2] | <a.c>
```

In this book, we'll usually write regular expression without quotes, like `\..`. If we need to emphasize what you'll actually type, we'll surround it

with quotes and add extra escapes, like "\\\\".

If \ is used as an escape character in regular expressions, how do you match a literal \? Well, you need to escape it, creating the regular expression \\\. To create that regular expression, you need to use a string, which also needs to escape \\. That means to match a literal \ you need to write "\\\\\" — you need four backslashes to match one!

```
x <- "a\\b"  
str_view(x)  
#> [1] | a\b  
str_view(x, "\\\\")  
#> [1] | a<|>b
```

Alternatively, you might find it easier to use the raw strings you learned about in [Section 16.2.2](#)). That lets you to avoid one layer of escaping:

```
str_view(x, r"{}\\")  
#> [1] | a<|>b
```

If you're trying to match a literal ., \$, |, *, +, ?, {, }, (,), there's an alternative to using a backslash escape: you can use a character class: [.], [\$], [|] ... all match the literal values.

```
str_view(c("abc", "a.c", "a*c", "a c"), "a[.]c")  
#> [2] | <a.c>  
str_view(c("abc", "a.c", "a*c", "a c"), ".[*]c")  
#> [3] | <a*c>
```

The full set of metacharacters is .^\$\\|*+?{}[](). In general, look at punctuation characters with suspicion; if your regular expression isn't matching what you think it should, check if you've used any of these characters.

17.4.2 Anchors

By default, regular expressions will match any part of a string. If you want to match at the start or end of the string you need to **anchor** the regular expression using `^` to match the start of the string or `$` to match the end of the string:

```
str_view(fruit, "^a")
#> [1] | <a>apple
#> [2] | <a>pricot
#> [3] | <a>vocado
str_view(fruit, "a$")
#> [4] | banan<a>
#> [15] | cherimoy<a>
#> [30] | feijo<a>
#> [36] | guav<a>
#> [56] | papay<a>
#> [74] | satsum<a>
```

It's tempting to think that `$` should match the end of a string, because that's how we write dollar amounts, but it's not what regular expressions want.

To force a regular expression to only the full string, anchor it with both `^` and `$`:

```
str_view(fruit, "apple")
#> [1] | <apple>
#> [62] | pine<apple>
str_view(fruit, "^apple$")
#> [1] | <apple>
```

You can also match the boundary between words (i.e. the start or end of a word) with `\b`. This can be particularly useful when using RStudio's find and

replace tool. For example, if to find all uses of `sum()`, you can search for `\bsum\b` to avoid matching `summarize`, `summary`, `rowsum` and so on:

```
x <- c("summary(x)", "summarize(df)", "rowsum(x)", "sum(str_view(x, "sum"))")
#> [1] | <sum>mary(x)
#> [2] | <sum>arize(df)
#> [3] | row<sum>(x)
#> [4] | <sum>(x)
str_view(x, "\bsum\b")
#> [4] | <sum>(x)
```

When used alone, anchors will produce a zero-width match:

```
str_view("abc", c("$", "^", "\b"))
#> [1] | abc<>
#> [2] | <>abc
#> [3] | <>abc<>
```

This helps you understand what happens when you replace a standalone anchor:

```
str_replace_all("abc", c("$", "^", "\b"), "--")
#> [1] "abc--"    "--abc"    "--abc--"
```

17.4.3 Character classes

A **character class**, or character **set**, allows you to match any character in a set. As we discussed above, you can construct your own sets with `[]`, where `[abc]` matches a, b, or c. There are three characters that have special meaning inside of `[]`:

- defines a range, e.g. `[a–z]` matches any lower case letter and `[0–9]` matches any number.
- ^ takes the inverse of the set, e.g. `[^abc]` matches anything except a, b, or c.
- \ escapes special characters, so `[\^\-\\]` matches ^, –, or \.

Here are few examples:

```
x <- "abcd ABCD 12345 -!@#%."
str_view(x, "[abc]+")
#> [1] | <abc>d ABCD 12345 -!@#%.
str_view(x, "[a-z]+")
#> [1] | <abcd> ABCD 12345 -!@#%.
str_view(x, "[^a-z0-9]+")
#> [1] | abcd< ABCD >12345< -!@#%.>

# You need an escape to match characters that are otherwise
# special inside of []
str_view("a-b-c", "[a-c]")
#> [1] | <a>-<b>-<c>
str_view("a-b-c", "[a\\-c]")
#> [1] | <a><->b<-><c>
```

Some character classes are used so commonly that they get their own shortcut. You've already seen `.`, which matches any character apart from a newline. There are three other particularly useful pairs⁶:

- \d matches any digit;
\D matches anything that isn't a digit.
- \s matches any whitespace (e.g. space, tab, newline);
\S matches anything that isn't whitespace.
- \w matches any “word” character, i.e. letters and numbers;
\W matches any “non-word” character.

The following code demonstrates the six shortcuts with a selection of letters, numbers, and punctuation characters.

```
x <- "abcd ABCD 12345 -!@#%."
str_view(x, "\\d+")
#> [1] | abcd ABCD <12345> -!@#%.
str_view(x, "\\D+")
#> [1] | <abcd ABCD >12345< -!@#%.>
str_view(x, "\\w+")
#> [1] | <abcd> <ABCD> <12345> -!@#%.
str_view(x, "\\W+")
#> [1] | abcd< >ABCD< >12345< -!@#%.>
str_view(x, "\\s+")
#> [1] | abcd< >ABCD< >12345< >-!@#%.
str_view(x, "\\S+")
#> [1] | <abcd> <ABCD> <12345> <-!@#%.>
```

17.4.4 Quantifiers

Quantifiers control how many times a pattern matches. In [Section 17.2](#) you learned about `?` (0 or 1 matches), `+` (1 or more matches), and `*` (0 or more matches). For example, `colou?r` will match American or British spelling, `\d+` will match one or more digits, and `\s?` will optionally match a single item of whitespace. You can also specify the number of matches precisely with `{}`:

- `{n}` matches exactly n times.
- `{n,}` matches at least n times.
- `{n,m}` matches between n and m times.

The following code shows how this works for a few simple examples:

```
x <- "-- -x- -xx- -xxx- -xxxx- -xxxxx--"
str_view(x, "-x?--")      # [0, 1]
#> [1] | <--> <-x-> -xx- -xxx- -xxxx- -xxxxx-
```

```
str_view(x, "-x+-")      # [1, Inf)
#> [1] | -- <-x-> <-xx-> <-xxx-> <-xxxx-> <-xxxxx->
str_view(x, "-x*")       # [0, Inf)
#> [1] | <--> <-x-> <-xx-> <-xxx-> <-xxxx-> <-xxxxx->
str_view(x, "-x{2}-")    # [2, 2]
#> [1] | -- -x- <-xx-> -xxx- -xxxx- -xxxxx-
str_view(x, "-x{2,}-")   # [2, Inf)
#> [1] | -- -x- <-xx-> <-xxx-> <-xxxx-> <-xxxxx->
str_view(x, "-x{2,3}-")  # [2, 3]
#> [1] | -- -x- <-xx-> <-xxx-> -xxxx- -xxxxx-
```

17.4.5 Operator precedence and parentheses

What does `ab+` match? Does it match “a” followed by one or more “b”s, or does it match “ab” repeated any number of times? What does `^a|b$` match? Does it match the complete string a or the complete string b, or does it match a string starting with a or a string starting with “b”?

The answer to these questions is determined by operator precedence, similar to the PEMDAS or BEDMAS rules you might have learned in school. You know that `a + b * c` is equivalent to `a + (b * c)` not `(a + b) * c` because `*` has higher precedence and `+` has lower precedence: you compute `*` before `+`.

Similarly, regular expressions have their own precedence rules: quantifiers have high precedence and alternation has low precedence which means that `ab+` is equivalent to `a(b+)`, and `^a|b$` is equivalent to `(^a)|(b$)`. Just like with algebra, you can use parentheses to override the usual order. But unlike algebra you’re unlikely to remember the precedence rules for regexes, so feel free to use parentheses liberally.

17.4.6 Grouping and capturing

As well overriding operator precedence, parentheses have another important effect: they create **capturing groups** that allow you to use sub-components of the match.

The first way to use a capturing group is to refer back to it within a match with **back reference**: `\1` refers to the match contained in the first parenthesis, `\2` in the second parenthesis, and so on. For example, the following pattern finds all fruits that have a repeated pair of letters:

```
str_view(fruit, "(..)\\1")
#> [4] | b<anan>a
#> [20] | <coco>nut
#> [22] | <cucu>mber
#> [41] | <juju>be
#> [56] | <papa>ya
#> [73] | s<alal> berry
```

And this one finds all words that start and end with the same pair of letters:

```
str_view(words, "^(..).*\\1$")
#> [152] | <church>
#> [217] | <decide>
#> [617] | <photograph>
#> [699] | <require>
#> [739] | <sense>
```

You can also use back references in `str_replace()`. For example, this code switches the order of the second and third words in `sentences`:

```
sentences |>
  str_replace("(\\w+) (\\w+) (\\w+)", "\\1 \\3 \\2") |>
  str_view()
#> [1] | The canoe birch slid on the smooth planks.
#> [2] | Glue sheet the to the dark blue background.
```

```
#> [3] | It's to easy tell the depth of a well.  
#> [4] | These a days chicken leg is a rare dish.  
#> [5] | Rice often is served in round bowls.  
#> [6] | The of juice lemons makes fine punch.  
#> [7] | The was box thrown beside the parked truck.  
#> [8] | The were hogs fed chopped corn and garbage.  
#> [9] | Four of hours steady work faced us.  
#> [10] | A size large in stockings is hard to sell.  
#> ... and 710 more
```

If you want extract the matches for each group you can use `str_match()`. But `str_match()` returns a matrix, so it's not particularly easy to work with⁷:

```
sentences |>  
  str_match("the (\w+) (\w+)") |>  
  head()  
#>      [,1]          [,2]      [,3]  
#> [1,"the smooth planks" "smooth" "planks"  
#> [2,"the sheet to"      "sheet"   "to"  
#> [3,"the depth of"     "depth"   "of"  
#> [4,NA                 NA       NA  
#> [5,NA                 NA       NA  
#> [6,NA                 NA       NA
```

You could convert to a tibble and name the columns:

```
sentences |>  
  str_match("the (\w+) (\w+)") |>  
  as_tibble(.name_repair = "minimal") |>  
  set_names("match", "word1", "word2")  
#> # A tibble: 720 × 3  
#>   match           word1    word2  
#>   <chr>          <chr>    <chr>  
#> 1 the smooth planks smooth planks
```

```
#> 2 the sheet to      sheet to
#> 3 the depth of      depth of
#> 4 <NA>              <NA>   <NA>
#> 5 <NA>              <NA>   <NA>
#> 6 <NA>              <NA>   <NA>
#> # ... with 714 more rows
```

But then you've basically recreated your own version of `separate_wider_regex()`. Indeed, behind the scenes, `separate_wider_regex()` converts your vector of patterns to a single regex that uses grouping to capture the named components.

Occasionally, you'll want to use parentheses without creating matching groups. You can create a non-capturing group with `(?:)`.

```
x <- c("a gray cat", "a grey dog")
str_match(x, "gr(e|a)y")
#>      [,1]    [,2]
#> [1,] "gray"  "a"
#> [2,] "grey"   "e"
str_match(x, "gr(?:e|a)y")
#>      [,1]
#> [1,] "gray"
#> [2,] "grey"
```

17.4.7 Exercises

1. How would you match the literal string `"' \ ?` How about `"$^$"`?
2. Explain why each of these patterns don't match a `\:` `"\"`, `"\\\"`, `"\\\\\"`.
3. Given the corpus of common words in `stringr::words`, create regular expressions that find all words that:
 - a. Start with "y".

- b. Don't start with "y".
 - c. End with "x".
 - d. Are exactly three letters long. (Don't cheat by using `str_length()`!)
 - e. Have seven letters or more.
 - f. Contain a vowel-consonant pair.
 - g. Contain at least two vowel-consonant pairs in a row.
 - h. Only consist of repeated vowel-consonant pairs.
4. Create 11 regular expressions that match the British or American spellings for each of the following words: grey/gray, modelling/modeling, summarize/summarize, aluminium/aluminum, defence/defense, analog/analogue, center/centre, sceptic/skeptic, aeroplane/airplane, arse/ass, doughnut/donut. Try and make the shortest possible regex!
5. Switch the first and last letters in `words`. Which of those strings are still words?
6. Describe in words what these regular expressions match: (read carefully to see if each entry is a regular expression or a string that defines a regular expression.)
- a. `^.*$`
 - b. `"\\{.\\}+\\}"`
 - c. `\\d{4}-\\d{2}-\\d{2}`
 - d. `"\\\\\\\\{4}"`
 - e. `\\.\\.\\..\\..`
 - f. `(.)\\1\\1`
 - g. `"(..)\\1"`
7. Solve the beginner regexp crosswords at
<https://regexecrossword.com/challenges/beginner>.

17.5 Pattern control

It's possible to exercise extra control over the details of the match by using a pattern object instead of just a string. This allows you control the so called regex flags and match various types of fixed strings, as described below.

17.5.1 Regex flags

There are a number of settings that can use to control the details of the regexp. These settings are often called **flags** in other programming languages. In stringr, you can use these by wrapping the pattern in a call to `regex()`. The most useful flag is probably `ignore_case = TRUE` because it allows characters to match either their uppercase or lowercase forms:

```
bananas <- c("banana", "Banana", "BANANA")
str_view(bananas, "banana")
#> [1] | <banana>
str_view(bananas, regex("banana", ignore_case = TRUE))
#> [1] | <banana>
#> [2] | <Banana>
#> [3] | <BANANA>
```

If you're doing a lot of work with multiline strings (i.e. strings that contain `\n`), `dotall` and `multiline` may also be useful:

- `dotall = TRUE` lets `.` match everything, including `\n`:

```
x <- "Line 1\nLine 2\nLine 3"
str_view(x, ".Line")
str_view(x, regex(".Line", dotall = TRUE))
#> [1] | Line 1<
```

```
#> | Line> 2<
#> | Line> 3
```

- `multiline = TRUE` makes `^` and `$` match the start and end of each line rather than the start and end of the complete string:

```
x <- "Line 1\nLine 2\nLine 3"
str_view(x, "^Line")
#> [1] | <Line> 1
#> | Line 2
#> | Line 3
str_view(x, regex("^Line", multiline = TRUE))
#> [1] | <Line> 1
#> | <Line> 2
#> | <Line> 3
```

Finally, if you're writing a complicated regular expression and you're worried you might not understand it in the future, you might try `comments = TRUE`. It tweaks the pattern language to ignore spaces and new lines, as well as everything after `#`. This allows you to use comments and whitespace to make complex regular expressions more understandable⁸, as in the following example:

```
phone <- regex(
  r"( # optional opening parens
    (\d{3}) # area code
    [)\-]? # optional closing parens, space, or dash
    (\d{3}) # another three numbers
    [\-]? # optional space or dash
    (\d{3}) # three more numbers
  )",
  comments = TRUE
)
str_match("514-791-8141", phone)
```

```
#>      [,1]      [,2]  [,3]  [,4]
#> [1,] "514-791-814" "514" "791" "814"
```

If you're using comments and want to match a space, newline, or #, you'll need to escape it:

```
str_view("x x #", regex(r"(x #)", comments = TRUE))
#> [1] | <x> <x> #
str_view("x x #", regex(r"(x\ \#)", comments = TRUE))
#> [1] | x <x #>
```

17.5.2 Fixed matches

You can opt-out of the regular expression rules by using `fixed()`:

```
str_view(c("", "a", "."), fixed(".")) 
#> [3] | <.>
```

`fixed()` also gives you the ability to ignore case:

```
str_view("x X", "X")
#> [1] | x <X>
str_view("x X", fixed("X", ignore_case = TRUE))
#> [1] | <x> <X>
```

If you're working with non-English text, you will probably want `coll()` instead of `fixed()`, as it implements the full rules for capitalization as used by the `locale` you specify. See [Section 16.6](#) for more details on locales.

```
str_view("i İ ı İ", fixed("İ", ignore_case = TRUE))
#> [1] | i <İ> ı İ
```

```
str_view("i ī ı I", coll("İ", ignore_case = TRUE, locale  
#> [1] | <i> <I> ı I
```

17.6 Practice

To put these ideas into practice we'll solve a few semi-authentic problems next. We'll discuss three general techniques:

1. checking your work by creating simple positive and negative controls
2. combining regular expressions with Boolean algebra
3. creating complex patterns using string manipulation

17.6.1 Check your work

First, let's find all sentences that start with "The". Using the `^` anchor alone is not enough:

```
str_view(sentences, "^The")  
#> [1] | <The> birch canoe slid on the smooth planks.  
#> [4] | <The>se days a chicken leg is a rare dish.  
#> [6] | <The> juice of lemons makes fine punch.  
#> [7] | <The> box was thrown beside the parked truck.  
#> [8] | <The> hogs were fed chopped corn and garbage.  
#> [11] | <The> boy was there when the sun rose.  
#> [13] | <The> source of the huge river is the clear sp  
#> [18] | <The> soft cushion broke the man's fall.  
#> [19] | <The> salt breeze came across from the sea.  
#> [20] | <The> girl at the booth sold fifty bonds.  
#> ... and 267 more
```

Because that pattern also matches sentences starting with words like `They` or `These`. We need to make sure that the “e” is the last letter in the word, which we can do by adding adding a word boundary:

```
str_view(sentences, "^The\\b")  
#> [1] | <The> birch canoe slid on the smooth planks.  
#> [6] | <The> juice of lemons makes fine punch.  
#> [7] | <The> box was thrown beside the parked truck.  
#> [8] | <The> hogs were fed chopped corn and garbage.  
#> [11] | <The> boy was there when the sun rose.  
#> [13] | <The> source of the huge river is the clear sp  
#> [18] | <The> soft cushion broke the man's fall.  
#> [19] | <The> salt breeze came across from the sea.  
#> [20] | <The> girl at the booth sold fifty bonds.  
#> [21] | <The> small pup gnawed a hole in the sock.  
#> ... and 246 more
```

What about finding all sentences that begin with a pronoun?

```
str_view(sentences, "^She|He|It|They\\b")  
#> [3] | <It>'s easy to tell the depth of a well.  
#> [15] | <He>lп the woman get back to her feet.  
#> [27] | <He>r purse was full of useless trash.  
#> [29] | <It> snowed, rained, and hailed the same morn  
#> [63] | <He> ran half way to the hardware store.  
#> [90] | <He> lay prone and hardly moved a limb.  
#> [116] | <He> ordered peach pie with ice cream.  
#> [118] | <He>mp is a weed found in parts of the tropic  
#> [127] | <It> caught its hind paw in a rusty trap.  
#> [132] | <He> said the same phrase thirty times.  
#> ... and 53 more
```

A quick inspection of the results shows that we're getting some spurious matches. That's because we've forgotten to use parentheses:

```
str_view(sentences, "^(She|He|It|They)\\b")
#> [3] <It>'s easy to tell the depth of a well.
#> [29] <It> snowed, rained, and hailed the same morn
#> [63] <He> ran half way to the hardware store.
#> [90] <He> lay prone and hardly moved a limb.
#> [116] <He> ordered peach pie with ice cream.
#> [127] <It> caught its hind paw in a rusty trap.
#> [132] <He> said the same phrase thirty times.
#> [153] <He> broke a new shoelace that day.
#> [159] <She> sewed the torn coat quite neatly.
#> [168] <He> knew the skill of the great young actres
#> ... and 47 more
```

You might wonder how you might spot such a mistake if it didn't occur in the first few matches. A good technique is to create a few positive and negative matches and use them to test that your pattern works as expected:

```
pos <- c("He is a boy", "She had a good time")
neg <- c("Shells come from the sea", "Hadley said 'It's

pattern <- "^(She|He|It|They)\\b"
str_detect(pos, pattern)
#> [1] TRUE TRUE
str_detect(neg, pattern)
#> [1] FALSE FALSE
```

It's typically much easier to come up with good positive examples than negative examples, because it takes a while before you're good enough

with regular expressions to predict where your weaknesses are. Nevertheless, they're still useful: as you work on the problem you can slowly accumulate a collection of your mistakes, ensuring that you never make the same mistake twice.

17.6.2 Boolean operations

Imagine we want to find words that only contain consonants. One technique is to create a character class that contains all letters except for the vowels (`[^aeiou]`), then allow that to match any number of letters (`[^aeiou]+`), then force it to match the whole string by anchoring to the beginning and the end (`^[^aeiou]+$`):

```
str_view(words, "^[^aeiou]+$")
#> [123] | <by>
#> [249] | <dry>
#> [328] | <fly>
#> [538] | <mrs>
#> [895] | <try>
#> [952] | <why>
```

But you can make this problem a bit easier by flipping the problem around. Instead of looking for words that contain only consonants, we could look for words that don't contain any vowels:

```
str_view(words[!str_detect(words, "[aeiou"]))]
#> [1] | by
#> [2] | dry
#> [3] | fly
#> [4] | mrs
#> [5] | try
#> [6] | why
```

This is a useful technique whenever you're dealing with logical combinations, particularly those involving “and” or “not”. For example, imagine if you want to find all words that contain “a” and “b”. There's no “and” operator built in to regular expressions so we have to tackle it by looking for all words that contain an “a” followed by a “b”, or a “b” followed by an “a”:

```
str_view(words, "a.*b|b.*a")
#> [2] | <ab>le
#> [3] | <ab>out
#> [4] | <ab>solute
#> [62] | <availab>le
#> [66] | <ba>by
#> [67] | <ba>ck
#> [68] | <ba>d
#> [69] | <ba>g
#> [70] | <bala>nce
#> [71] | <ba>ll
#> ... and 20 more
```

It's simpler to combine the results of two calls to `str_detect()`:

```
words[str_detect(words, "a") & str_detect(words, "b")]
#> [1] "able"        "about"       "absolute"     "available"
#> [7] "bad"         "bag"        "balance"      "ball"
#> [13] "base"       "basis"       "bear"        "beat"
#> [19] "black"      "board"      "boat"        "break"
#> [25] "debate"     "husband"    "labour"      "maybe"
```

What if we wanted to see if there was a word that contains all vowels? If we did it with patterns we'd need to generate $5!$ (120) different patterns:

```
words[str_detect(words, "a.*e.*i.*o.*u")]
# ...
words[str_detect(words, "u.*o.*i.*e.*a")]
```

It's much simpler to combine five calls to `str_detect()`:

```
words [
  str_detect(words, "a") &
  str_detect(words, "e") &
  str_detect(words, "i") &
  str_detect(words, "o") &
  str_detect(words, "u")
]
#> character(0)
```

In general, if you get stuck trying to create a single regexp that solves your problem, take a step back and think if you could break the problem down into smaller pieces, solving each challenge before moving onto the next one.

17.6.3 Creating a pattern with code

What if we wanted to find all `sentences` that mention a color? The basic idea is simple: we just combine alternation with word boundaries.

```
str_view(sentences, "\\b(red|green|blue)\\b")
#> [2] | Glue the sheet to the dark <blue> background.
#> [26] | Two <blue> fish swam in the tank.
#> [92] | A wisp of cloud hung in the <blue> air.
#> [148] | The spot on the blotter was made by <green> i
#> [160] | The sofa cushion is <red> and of light weight
#> [174] | The sky that morning was clear and bright <bl
#> [204] | A <blue> crane is a tall wading bird.
#> [217] | It is hard to erase <blue> or <red> ink.
```

```
#> [224] | The lamp shone with a steady <green> flame.  
#> [247] | The box is held by a bright <red> snapper.  
#> ... and 16 more
```

But as the number of colors grows, it would quickly get tedious to construct this pattern by hand. Wouldn't it be nice if we could store the colors in a vector?

```
rgb <- c("red", "green", "blue")
```

Well, we can! We'd just need to create the pattern from the vector using `str_c()` and `str_flatten()`:

```
str_c("\b(", str_flatten(rgb), "|"), ")\\b"  
#> [1] "\b(red|green|blue)\b"
```

We could make this pattern more comprehensive if we had a good list of colors. One place we could start from is the list of built-in colors that R can use for plots:

```
str_view(colors())  
#> [1] | white  
#> [2] | aliceblue  
#> [3] | antiquewhite  
#> [4] | antiquewhite1  
#> [5] | antiquewhite2  
#> [6] | antiquewhite3  
#> [7] | antiquewhite4  
#> [8] | aquamarine  
#> [9] | aquamarine1  
#> [10] | aquamarine2  
#> ... and 647 more
```

But let's first eliminate the numbered variants:

```
cols <- colors()
cols <- cols[!str_detect(cols, "\\\d")]
str_view(cols)
#> [1] | white
#> [2] | aliceblue
#> [3] | antiquewhite
#> [4] | aquamarine
#> [5] | azure
#> [6] | beige
#> [7] | bisque
#> [8] | black
#> [9] | blanchedalmond
#> [10] | blue
#> ... and 133 more
```

Then we can turn this into one giant pattern. We won't show the pattern here because it's huge, but you can see it working:

```
pattern <- str_c("\b(", str_flatten(cols, "|"), ")\b")
str_view(sentences, pattern)
#> [2] | Glue the sheet to the dark <blue> background.
#> [12] | A rod is used to catch <pink> <salmon>.
#> [26] | Two <blue> fish swam in the tank.
#> [66] | Cars and busses stalled in <snow> drifts.
#> [92] | A wisp of cloud hung in the <blue> air.
#> [112] | Leaves turn <brown> and <yellow> in the fall.
#> [148] | The spot on the blotter was made by <green> i
#> [149] | Mud was spattered on the front of his <white>
#> [160] | The sofa cushion is <red> and of light weight
#> [167] | The office paint was a dull, sad <tan>.
#> ... and 53 more
```

In this example, `cols` only contains numbers and letters so you don't need to worry about metacharacters. But in general, whenever you create patterns from existing strings it's wise to run them through `str_escape()` to ensure they match literally.

17.6.4 Exercises

1. For each of the following challenges, try solving it by using both a single regular expression, and a combination of multiple `str_detect()` calls.
 - a. Find all `words` that start or end with `x`.
 - b. Find all `words` that start with a vowel and end with a consonant.
 - c. Are there any `words` that contain at least one of each different vowel?
2. Construct patterns to find evidence for and against the rule “i before e except after c”?
3. `colors()` contains a number of modifiers like “lightgray” and “darkblue”. How could you automatically identify these modifiers? (Think about how you might detect and then remove the colors that are modified).
4. Create a regular expression that finds any base R dataset. You can get a list of these datasets via a special use of the `data()` function: `data(package = "datasets")$results[, "Item"]`. Note that a number of old datasets are individual vectors; these contain the name of the grouping “data frame” in parentheses, so you'll need to strip those off.

17.7 Regular expressions in other places

Just like in the stringr and tidyverse functions, there are many other places in R where you can use regular expressions. The following sections describe some other useful functions in the wider tidyverse and base R.

17.7.1 tidyverse

There are three other particularly useful places where you might want to use a regular expressions

- `matches(pattern)` will select all variables whose name matches the supplied pattern. It's a “tidyselect” function that you can use anywhere in any tidyverse function that selects variables (e.g. `select()`, `rename_with()` and `across()`).
- `pivot_longer()`'s `names_pattern` argument takes a vector of regular expressions, just like `separate_with_regex()`. It's useful when extracting data out of variable names with a complex structure
- The `delim` argument in `separate_delim_longer()` and `separate_delim_wider()` usually matches a fixed string, but you can use `regex()` to make it match a pattern. This is useful, for example, if you want to match a comma that is optionally followed by a space, i.e. `regex(", ?")`.

17.7.2 Base R

`apropos(pattern)` searches all objects available from the global environment that match the given pattern. This is useful if you can't quite remember the name of a function:

```
apropos("replace")
#> [1] "%+replace%"           "replace"            "replace_na"
```

```
#> [4] "setReplaceMethod" "str_replace"      "str_replac
#> [7] "str_replace_na"    "theme_replace"
```

`list.files(path, pattern)` lists all files in path that match a regular expression pattern. For example, you can find all the R Markdown files in the current directory with:

```
head(list.files(pattern = "\\.Rmd$"))
#> character(0)
```

It's worth noting that the pattern language used by base R is very slightly different to that used by stringr. That's because stringr is built on top of the [stringi package](#), which is in turn built on top of the [ICU engine](#), whereas base R functions use either the [TRE engine](#) or the [PCRE engine](#), depending on whether or not you've set `perl = TRUE`. Fortunately, the basics of regular expressions are so well established that you'll encounter few variations when working with the patterns you'll learn in this book. You only need to be aware of the difference when you start to rely on advanced features like complex Unicode character ranges or special features that use the `(?...)` syntax.

17.8 Summary

With every punctuation character potentially overloaded with meaning, regular expressions are one of the most compact languages out there. They're definitely confusing at first but as you train your eyes to read them and your brain to understand them, you unlock a powerful skill that you can use in R and in many other places.

In this chapter, you've started your journey to become a regular expression master by learning the most useful stringr functions and the

most important components of the regular expression language. And there are plenty of resources to learn more.

A good place to start is `vignette("regular-expressions", package = "stringr")`: it documents the full set of syntax supported by stringr. Another useful reference is <https://www.regular-expressions.info/>. It's not R specific, but you can use it to learn about the most advanced features of regexes and how they work under the hood.

It's also good to know that stringr is implemented on top of the stringi package by Marek Gagolewsk. If you're struggling to find a function that does what you need in stringr, don't be afraid to look in stringi. You'll find stringi very easy to pick up because it follows many of the the same conventions as stringr.

In the next chapter, we'll talk about a data structure closely related to strings: factors. Factors are used to represent categorical data in R, i.e. data with a fixed and known set of possible values identified by a vector of strings.

1. You can pronounce it with either a hard-g (reg-x) or a soft-g (rej-x). 
2. You'll learn how to escape these special meanings in [Section 17.4.1.](#) 
3. Well, any character apart from `\n`. 
4. This gives us the proportion of **names** that contain an “x”; if you wanted the proportion of babies with a name containing an x, you'd need to perform a weighted mean. 
5. We wish we could reassure you that you'd never see something this weird in real life, but unfortunately over the course of your career you're likely to see much weirder! 

6. Remember, to create a regular expression containing \d or \s, you'll need to escape the \ for the string, so you'll type "\\\d" or "\\\s".

7. Mostly because we never discuss matrices in this book!

8. comments = TRUE is particularly effective in combination with a raw string, as we use here.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with Quarto.

i You are reading the work-in-progress second edition of R for Data Science. This chapter is largely complete and just needs final proof reading. You can find the complete first edition at <https://r4ds.had.co.nz>.

18.1 Introduction

Factors are used for categorical variables, variables that have a fixed and known set of possible values. They are also useful when you want to display character vectors in a non-alphabetical order.

We'll start by motivating why factors are needed for data analysis and how you can create them with `factor()`. We'll then introduce you to the `gss_cat` dataset which contains a bunch of categorical variables to experiment with. You'll then use that dataset to practice modifying the order and values of factors, before we finish up with a discussion of ordered factors.

18.1.1 Prerequisites

Base R provides some basic tools for creating and manipulating factors. We'll supplement these with the **forcats** package, which is part of the core tidyverse. It provides tools for dealing with **categorical** variables (and it's an anagram of factors!) using a wide range of helpers for working with factors.

```
library(tidyverse)
```

18.2 Factor basics

Imagine that you have a variable that records month:

```
x1 <- c("Dec", "Apr", "Jan", "Mar")
```

Using a string to record this variable has two problems:

1. There are only twelve possible months, and there's nothing saving you from typos:

```
x2 <- c("Dec", "Apr", "Jam", "Mar")
```

2. It doesn't sort in a useful way:

```
sort(x1)
#> [1] "Apr" "Dec" "Jan" "Mar"
```

You can fix both of these problems with a factor. To create a factor you must start by creating a list of the valid **levels**:

```
month_levels <- c(
  "Jan", "Feb", "Mar", "Apr", "May", "Jun",
  "Jul", "Aug", "Sep", "Oct", "Nov", "Dec"
)
```

Now you can create a factor:

```
y1 <- factor(x1, levels = month_levels)
y1
#> [1] Dec Apr Jan Mar
#> Levels: Jan Feb Mar Apr May Jun Jul Aug Sep Oct Nov D
```

```
sort(y1)
#> [1] Jan Mar Apr Dec
#> Levels: Jan Feb Mar Apr May Jun Jul Aug Sep Oct Nov D
```

And any values not in the level will be silently converted to NA:

```
y2 <- factor(x2, levels = month_levels)
y2
#> [1] Dec Apr <NA> Mar
#> Levels: Jan Feb Mar Apr May Jun Jul Aug Sep Oct Nov D
```

This seems risky, so you might want to use `fct()` instead:

```
y2 <- fct(x2, levels = month_levels)
#> Error in `fct()`:
#> ! All values of `x` must appear in `levels` or `na`
#> i Missing level: "Jan"
```

If you omit the levels, they'll be taken from the data in alphabetical order:

```
factor(x1)
#> [1] Dec Apr Jan Mar
#> Levels: Apr Dec Jan Mar
```

Sometimes you'd prefer that the order of the levels matches the order of the first appearance in the data. You can do that when creating the factor by setting levels to `unique(x)`, or after the fact, with `fct_inorder()`:

```
f1 <- factor(x1, levels = unique(x1))
f1
#> [1] Dec Apr Jan Mar
#> Levels: Dec Apr Jan Mar

f2 <- x1 |> factor() |> fct_inorder()
f2
#> [1] Dec Apr Jan Mar
#> Levels: Dec Apr Jan Mar
```

If you ever need to access the set of valid levels directly, you can do so with levels():

```
levels(f2)
#> [1] "Dec" "Apr" "Jan" "Mar"
```

You can also create a factor when reading your data with `readr` with col_factor():

```
csv <- "
month,value
Jan,12
Feb,56
Mar,12"

df <- read_csv(csv, col_types = cols(month = col_factor(df$month
#> [1] Jan Feb Mar
#> Levels: Jan Feb Mar Apr May Jun Jul Aug Sep Oct Nov D
```

18.3 General Social Survey

For the rest of this chapter, we're going to use `forcats::gss_cat`. It's a sample of data from the [General Social Survey](#), a long-running US survey conducted by the independent research organization NORC at the University of Chicago. The survey has thousands of questions, so in `gss_cat` Hadley selected a handful that will illustrate some common challenges you'll encounter when working with factors.

```
gss_cat
#> # A tibble: 21,483 × 9
#>   year marital      age race   rincome     part
#>   <int> <fct>     <int> <fct> <fct>       <fct>
#> 1 2000 Never married    26 White $8000 to 9999 Ind,
#> 2 2000 Divorced        48 White $8000 to 9999 Not
#> 3 2000 Widowed        67 White Not applicable Inde
#> 4 2000 Never married    39 White Not applicable Ind,
#> 5 2000 Divorced        25 White Not applicable Not
#> 6 2000 Married         25 White $20000 – 24999 Strc
#> # ... with 21,477 more rows
```

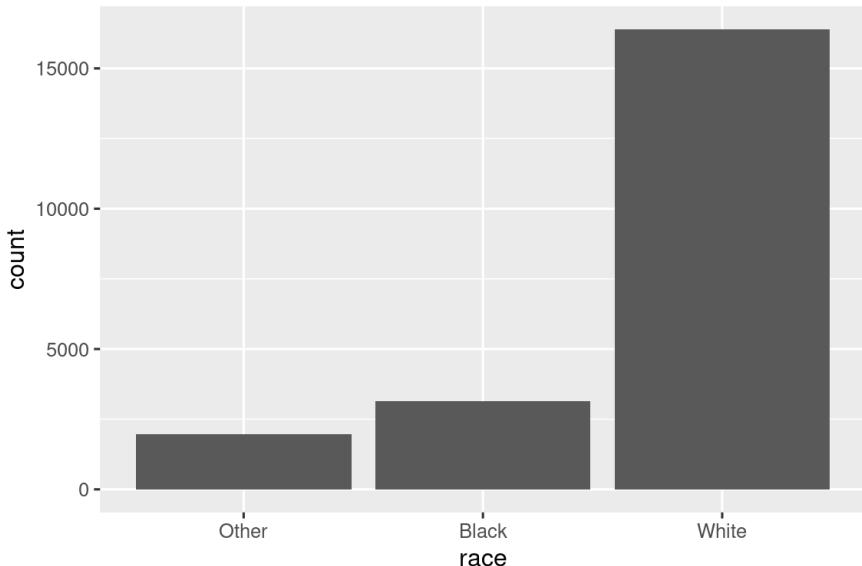

(Remember, since this dataset is provided by a package, you can get more information about the variables with `?gss_cat`.)

When factors are stored in a tibble, you can't see their levels so easily. One way to view them is with `count()`:

```
gss_cat |>
  count(race)
#> # A tibble: 3 × 2
#>   race     n
#>   <fct> <int>
#> 1 Other  1959
#> 2 Black  3129
#> 3 White 16395
```

Or with a bar chart:

```
ggplot(gss_cat, aes(x = race)) +  
  geom_bar()
```

When working with factors, the two most common operations are changing the order of the levels, and changing the values of the levels. Those operations are described in the sections below.

18.3.1 Exercise

1. Explore the distribution of `rincome` (reported income). What makes the default bar chart hard to understand? How could you improve the plot?
2. What is the most common `relig` in this survey? What's the most common `partyid`?

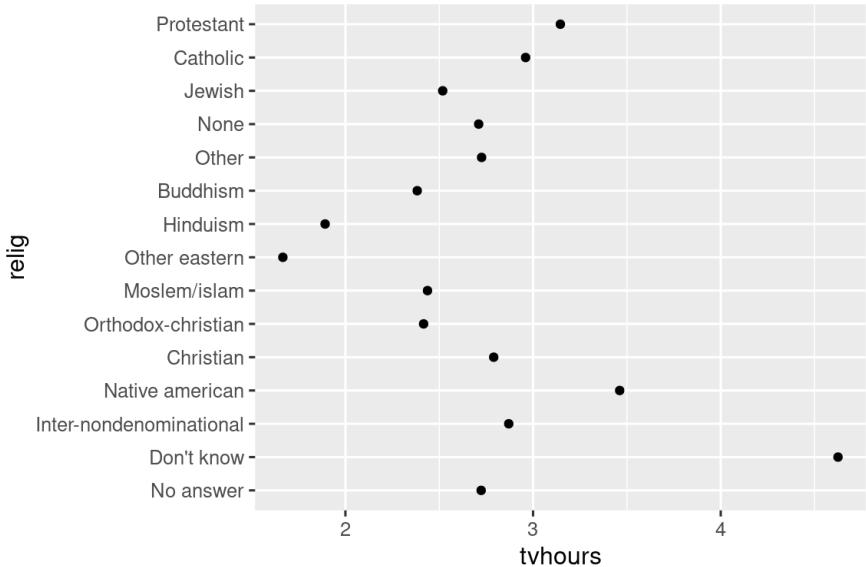

3. Which `relig` does `denom` (denomination) apply to? How can you find out with a table? How can you find out with a visualization?

18.4 Modifying factor order

It's often useful to change the order of the factor levels in a visualization. For example, imagine you want to explore the average number of hours spent watching TV per day across religions:

```
relig_summary <- gss_cat |>
  group_by(relig) |>
  summarize(
    age = mean(age, na.rm = TRUE),
    tvhours = mean(tvhours, na.rm = TRUE),
    n = n()
  )

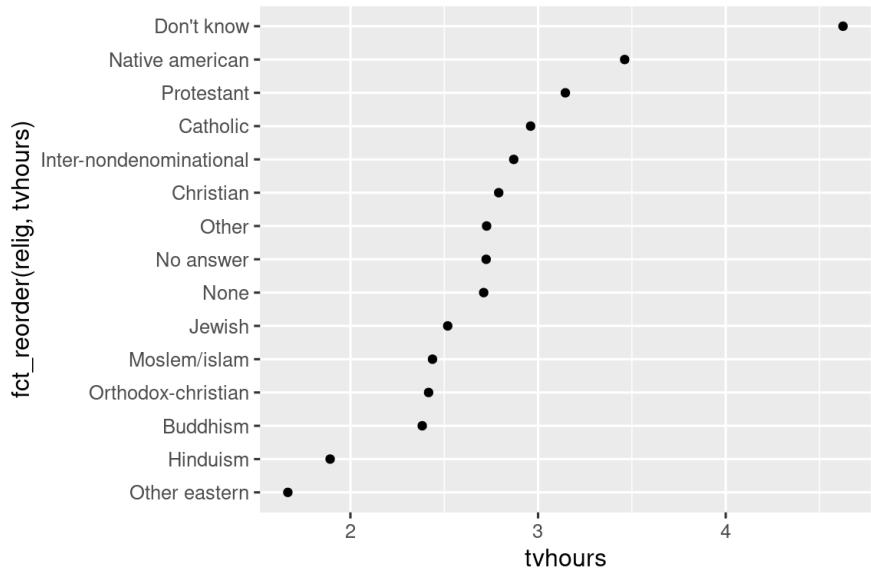

ggplot(relig_summary, aes(x = tvhours, y = relig)) +
  geom_point()
```

It is hard to read this plot because there's no overall pattern. We can improve it by reordering the levels of `relig` using `fct_reorder()`. `fct_reorder()` takes three arguments:

- `f`, the factor whose levels you want to modify.
- `x`, a numeric vector that you want to use to reorder the levels.
- Optionally, `fun`, a function that's used if there are multiple values of `x` for each value of `f`. The default value is `median`.

```
ggplot(relig_summary, aes(x = tvhours, y = fct_reorder(r  
geom_point()
```

Reordering religion makes it much easier to see that people in the “Don’t know” category watch much more TV, and Hinduism & Other Eastern religions watch much less.

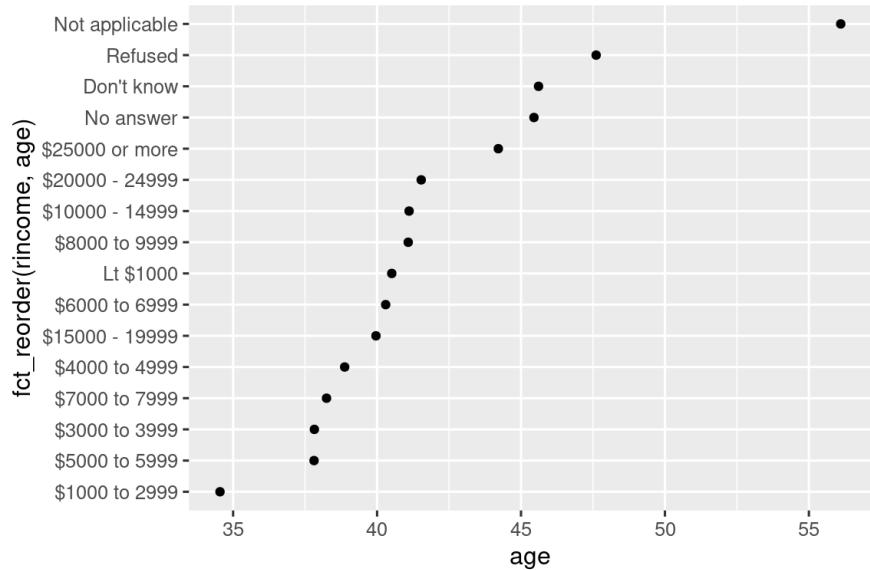

As you start making more complicated transformations, we recommend moving them out of `aes()` and into a separate `mutate()` step. For example, you could rewrite the plot above as:

```
relig_summary |>
  mutate(
    relig = fct_reorder(relig, tvhours)
  ) |>
  ggplot(aes(x = tvhours, y = relig)) +
  geom_point()
```

What if we create a similar plot looking at how average age varies across reported income level?

```
rincome_summary <- gss_cat |>
  group_by(rincome) |>
  summarize(
    age = mean(age, na.rm = TRUE),
    tvhours = mean(tvhours, na.rm = TRUE),
    n = n()
  )

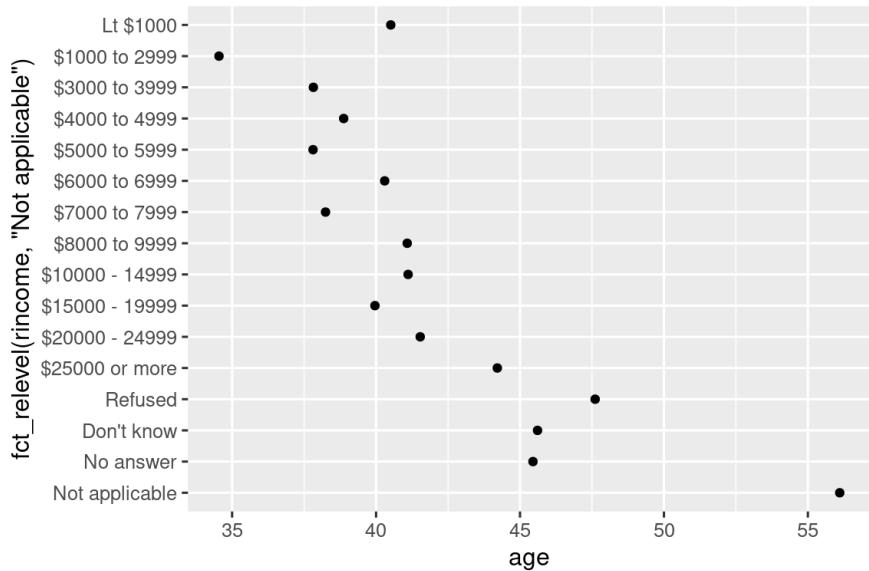

ggplot(rincome_summary, aes(x = age, y = fct_reorder(rin
  geom_point()
```

Here, arbitrarily reordering the levels isn't a good idea! That's because `rincome` already has a principled order that we shouldn't mess with. Reserve `fct_reorder()` for factors whose levels are arbitrarily ordered.

However, it does make sense to pull “Not applicable” to the front with the other special levels. You can use `fct_relevel()`. It takes a factor, `f`, and then any number of levels that you want to move to the front of the line.

```
ggplot(rincome_summary, aes(x = age, y = fct_relevel(rincom  
geom_point()
```

Why do you think the average age for “Not applicable” is so high?

Another type of reordering is useful when you are coloring the lines on a plot. `fct_reorder2(f, x, y)` reorders the factor `f` by the `y` values associated with the largest `x` values. This makes the plot easier to read because the colors of the line at the far right of the plot will line up with the legend.

```
#|  
#|      Rearranging the legend makes the plot easier to r
```

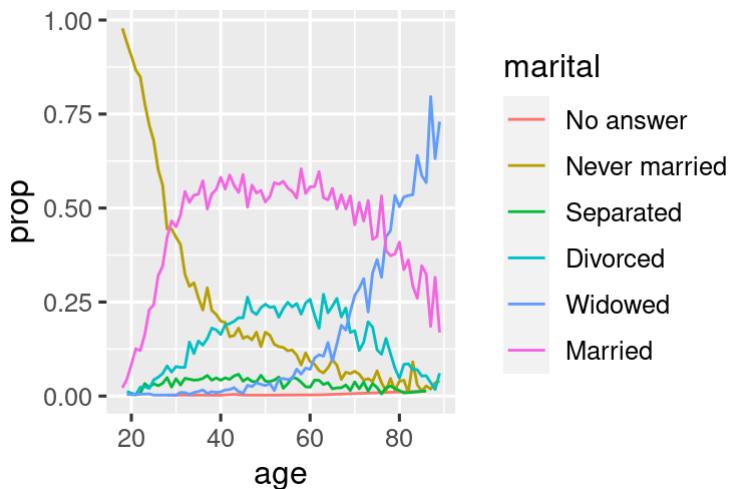

```

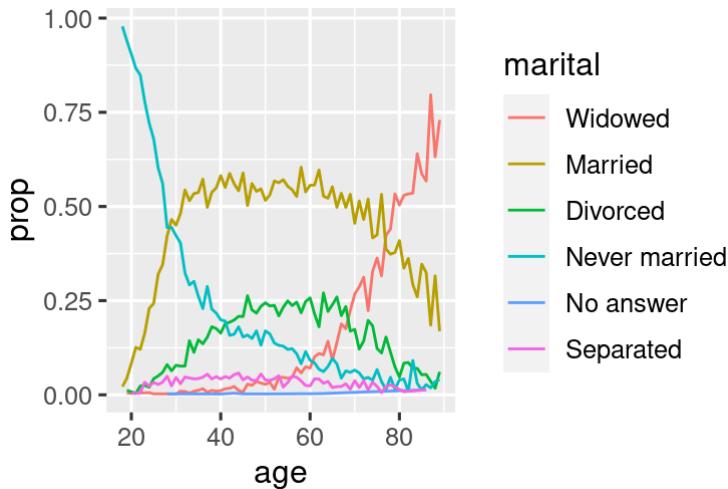

#|   legend colors now match the order of the lines or
#|   of the plot. You can see some unsurprising patterns
#|   never married decreases with age, married forms an
#|   shape, and widowed starts off low but increases after
#|   60.
by_age <- gss_cat |>
  filter(!is.na(age)) |>
  count(age, marital) |>
  group_by(age) |>
  mutate(
    prop = n / sum(n)
  )

ggplot(by_age, aes(x = age, y = prop, color = marital))
  geom_line(na.rm = TRUE)

ggplot(by_age, aes(x = age, y = prop, color = fct_reorder(
  geom_line() +
  labs(color = "marital")

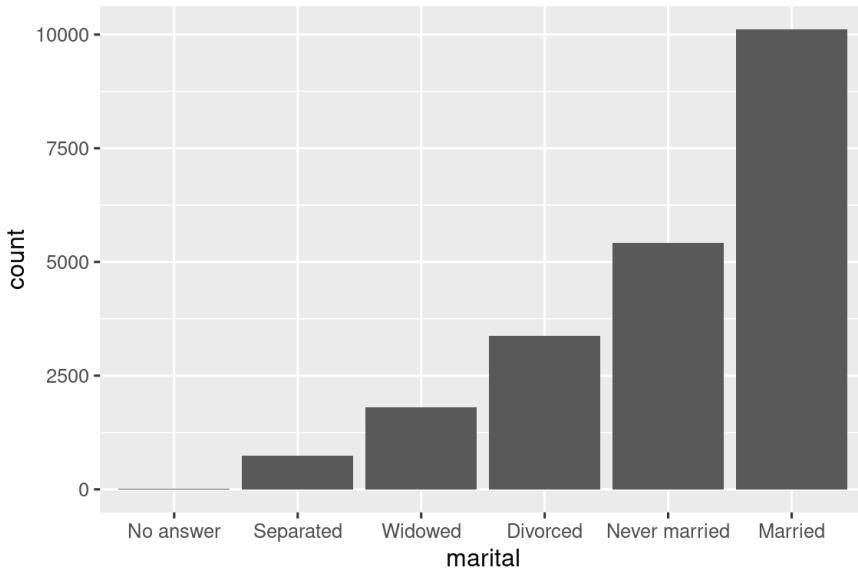

```

Finally, for bar plots, you can use `fct_infreq()` to order levels in decreasing frequency: this is the simplest type of reordering because it doesn't need any extra variables. Combine it with `fct_rev()` if you want them in increasing frequency so that in the bar plot largest values are on the right, not the left.

```
gss_cat |>
  mutate(marital = marital |> fct_infreq() |> fct_rev())
  ggplot(aes(x = marital)) +
  geom_bar()
```

18.4.1 Exercises

1. There are some suspiciously high numbers in `tvhours`. Is the mean a good summary?
2. For each factor in `gss_cat` identify whether the order of the levels is arbitrary or principled.
3. Why did moving “Not applicable” to the front of the levels move it to the bottom of the plot?

18.5 Modifying factor levels

More powerful than changing the orders of the levels is changing their values. This allows you to clarify labels for publication, and collapse levels for high-level displays. The most general and powerful tool is `fct_recode()`. It allows you to recode, or change, the value of each level. For example, take the `gss_cat$partyid`:

```
gss_cat |> count(partyid)
#> # A tibble: 10 × 2
#>   partyid          n
#>   <fct>        <int>
#> 1 No answer      154
#> 2 Don't know      1
#> 3 Other party    393
#> 4 Strong republican  2314
#> 5 Not str republican 3032
#> 6 Ind,near rep     1791
#> # ... with 4 more rows
```

The levels are terse and inconsistent. Let's tweak them to be longer and use a parallel construction. Like most rename and recoding functions in the tidyverse, the new values go on the left and the old values go on the right:

```
gss_cat |>
  mutate(
    partyid = fct_recode(partyid,
      "Republican, strong"      = "Strong republican",
      "Republican, weak"        = "Not str republican",
      "Independent, near rep"  = "Ind,near rep",
      "Independent, near dem"  = "Ind,near dem",
      "Democrat, weak"         = "Not str democrat",
      "Democrat, strong"       = "Strong democrat"
    )
  ) |>
  count(partyid)
#> # A tibble: 10 × 2
#>   partyid          n
#>   <fct>        <int>
#> 1 No answer      154
#> 2 Don't know      1
#> 3 Other party    393
```

```
#> 4 Republican, strong      2314  
#> 5 Republican, weak       3032  
#> 6 Independent, near rep  1791  
#> # ... with 4 more rows
```

`fct_recode()` will leave the levels that aren't explicitly mentioned as is, and will warn you if you accidentally refer to a level that doesn't exist.

To combine groups, you can assign multiple old levels to the same new level:

```
gss_cat |>  
  mutate(  
    partyid = fct_recode(partyid,  
      "Republican, strong"     = "Strong republican",  
      "Republican, weak"       = "Not str republican",  
      "Independent, near rep" = "Ind,near rep",  
      "Independent, near dem" = "Ind,near dem",  
      "Democrat, weak"        = "Not str democrat",  
      "Democrat, strong"      = "Strong democrat",  
      "Other"                 = "No answer",  
      "Other"                 = "Don't know",  
      "Other"                 = "Other party"  
    )  
  ) |>  
  count(partyid)  
#> # A tibble: 8 × 2  
#>   partyid           n  
#>   <fct>          <int>  
#> 1 Other            548  
#> 2 Republican, strong  2314  
#> 3 Republican, weak   3032  
#> 4 Independent, near rep 1791  
#> 5 Independent        4119  
#> 6 Independent, near dem 2499  
#> # ... with 2 more rows
```

Use this technique with care: if you group together categories that are truly different you will end up with misleading results.

If you want to collapse a lot of levels, `fct_collapse()` is a useful variant of `fct_recode()`. For each new variable, you can provide a vector of old levels:

```
gss_cat |>
  mutate(
    partyid = fct_collapse(partyid,
      "other" = c("No answer", "Don't know", "Other part",
      "rep" = c("Strong republican", "Not str republican",
      "ind" = c("Ind,near rep", "Independent", "Ind,near",
      "dem" = c("Not str democrat", "Strong democrat")
    )
  ) |>
  count(partyid)
#> # A tibble: 4 × 2
#>   partyid     n
#>   <fct>   <int>
#> 1 other      548
#> 2 rep        5346
#> 3 ind       8409
#> 4 dem       7180
```

Sometimes you just want to lump together the small groups to make a plot or table simpler. That's the job of the `fct_lump_*` family of functions. `fct_lump_lowfreq()` is a simple starting point that progressively lumps the smallest groups categories into “Other”, always keeping “Other” as the smallest category.

```
gss_cat |>
  mutate(relig = fct_lump_lowfreq(relig)) |>
  count(relig)
```

```
#> # A tibble: 2 × 2
#>   relig      n
#>   <fct>    <int>
#> 1 Protestant 10846
#> 2 Other     10637
```

In this case it's not very helpful: it is true that the majority of Americans in this survey are Protestant, but we'd probably like to see some more details! Instead, we can use the `fct_lump_n()` to specify that we want exactly 10 groups:

```
gss_cat |>
  mutate(relig = fct_lump_n(relig, n = 10)) |>
  count(relig, sort = TRUE) |>
  print(n = Inf)
#> # A tibble: 10 × 2
#>   relig              n
#>   <fct>            <int>
#> 1 Protestant        10846
#> 2 Catholic          5124
#> 3 None              3523
#> 4 Christian         689
#> 5 Other              458
#> 6 Jewish             388
#> 7 Buddhism           147
#> 8 Inter-nondenominational 109
#> 9 Moslem/islam       104
#> 10 Orthodox-christian 95
```

Read the documentation to learn about `fct_lump_min()` and `fct_lump_prop()` which are useful in other cases.

18.5.1 Exercises

1. How have the proportions of people identifying as Democrat, Republican, and Independent changed over time?

2. How could you collapse `rincome` into a small set of categories?

3. Notice there are 9 groups (excluding other) in the `fct_lump` example above. Why not 10? (Hint: type `?fct_lump`, and find the default for the argument `other_level` is “Other”.)

18.6 Ordered factors

Before we go on, there’s a special type of factor that needs to be mentioned briefly: ordered factors. Ordered factors, created with `ordered()`, imply a strict ordering and equal distance between levels: the first level is “less than” the second level by the same amount that the second level is “less than” the third level, and so on.. You can recognize them when printing because they use `<` between the factor levels:

```
ordered(c("a", "b", "c"))
#> [1] a b c
#> Levels: a < b < c
```

In practice, `ordered()` factors behave very similarly to regular factors. There are only two places where you might notice different behavior:

- If you map an ordered factor to color or fill in ggplot2, it will default to `scale_color_viridis() / scale_fill_viridis()`, a color scale that implies a ranking.
- If you use an ordered function in a linear model, it will use “polygonal contrasts”. These are mildly useful, but you are unlikely to have heard of them unless you have a PhD in Statistics, and even then you probably don’t routinely interpret them. If you want to learn more, we recommend `vignette("contrasts", package = "faux")` by Lisa DeBruine.

Given the arguable utility of these differences, we don't generally recommend using ordered factors.

18.7 Summary

This chapter introduced you to the handy `forcats` package for working with factors, introducing you to the most commonly used functions. `forcats` contains a wide range of other helpers that we didn't have space to discuss here, so whenever you're facing a factor analysis challenge that you haven't encountered before, I highly recommend skimming the [reference index](#) to see if there's a canned function that can help solve your problem.

If you want to learn more about factors after reading this chapter, we recommend reading Amelia McNamara and Nicholas Horton's paper, [*Wrangling categorical data in R*](#). This paper lays out some of the history discussed in [*stringsAsFactors: An unauthorized biography*](#) and [`stringsAsFactors = <sigh>`](#), and compares the tidy approaches to categorical data outlined in this book with base R methods. An early version of the paper helped motivate and scope the `forcats` package; thanks Amelia & Nick!

In the next chapter we'll switch gears to start learning about dates and times in R. Dates and times seem deceptively simple, but as you'll soon see, the more you learn about them, the more complex they seem to get!

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

19.1 Introduction

This chapter will show you how to work with dates and times in R. At first glance, dates and times seem simple. You use them all the time in your regular life, and they don't seem to cause much confusion. However, the more you learn about dates and times, the more complicated they seem to get!

To warm up think about how many days there are in a year, and how many hours there are in a day. You probably remembered that most years have 365 days, but leap years have 366. Do you know the full rule for determining if a year is a leap year¹? The number of hours in a day is a little less obvious: most days have 24 hours, but in places that use daylight saving time (DST), one day each year has 23 hours and another has 25.

Dates and times are hard because they have to reconcile two physical phenomena (the rotation of the Earth and its orbit around the sun) with a whole raft of geopolitical phenomena including months, time zones, and DST. This chapter won't teach you every last detail about dates and times, but it will give you a solid grounding of practical skills that will help you with common data analysis challenges.

We'll begin by showing you how to create date-times from various inputs, and then once you've got a date-time, how you can extract components like year, month, and day. We'll then dive into the tricky topic of working with time spans, which come in a variety of flavors depending on what you're trying to do. We'll conclude with a brief discussion of the additional challenges posed by time zones.

19.1.1 Prerequisites

This chapter will focus on the **lubridate** package, which makes it easier to work with dates and times in R. lubridate is not part of core tidyverse because you only need it when you're working with dates/times. We will also need nycflights13 for practice data.

```
library(tidyverse)
```

```
library(lubridate)
```

```
library(nycflights13)
```

19.2 Creating date/times

There are three types of date/time data that refer to an instant in time:

- A **date**. Tibbles print this as <date>.
- A **time** within a day. Tibbles print this as <time>.
- A **date-time** is a date plus a time: it uniquely identifies an instant in time (typically to the nearest second). Tibbles print this as <dttm>. Base R calls these POSIXct, but doesn't exactly trip off the tongue.

In this chapter we are going to focus on dates and date-times as R doesn't have a native class for storing times. If you need one, you can

use the **hms** package.

You should always use the simplest possible data type that works for your needs. That means if you can use a date instead of a date-time, you should. Date-times are substantially more complicated because of the need to handle time zones, which we'll come back to at the end of the chapter.

To get the current date or date-time you can use `today()` or `now()`:

```
today()
#> [1] "2023-01-19"
now()
#> [1] "2023-01-19 23:11:04 UTC"
```

Otherwise, the following sections describe the four ways you're likely to create a date/time:

- While reading a file with `readr`.
- From a string.
- From individual date-time components.
- From an existing date/time object.

19.2.1 During import

If your CSV contains an ISO8601 date or date-time, you don't need to do anything; `readr` will automatically recognize it:

```
csv <- "
  date,datetime
  2022-01-02,2022-01-02 05:12
"
read_csv(csv)
#> # A tibble: 1 × 2
#>   date      datetime
```

```
#> <date>      <dttm>
#> 1 2022-01-02 2022-01-02 05:12:00
```

If you haven't heard of **ISO8601** before, it's an international standard² for writing dates where the components of a date are organised from biggest to smallest separated by `-`. For example, in ISO8601 March 5 2022 is `2022-03-05`. ISO8601 dates can also include times, where hour, minute, and second are separated by `:`, and the date and time components are separated by either a `T` or a space. For example, you could write 4:26pm on March 5 2022 as either `2022-03-05 16:26` or `2022-03-05T16:26`.

For other date-time formats, you'll need to use `col_types` plus `col_date()` or `col_datetime()` along with a date-time format. The date-time format used by `readr` is a standard used across many programming languages, describing a date component with a `%` followed by a single character. For example, `%Y-%m-%d` specifies a date that's a year, `-`, month (as number) `-`, day. Table [Table 19.1](#) lists all the options.

Table 19.1: All date formats understood by `readr`

| Type | Code | Meaning | Example |
|-------|-----------------|------------------|----------|
| Year | <code>%Y</code> | 4 digit year | 2021 |
| | <code>%y</code> | 2 digit year | 21 |
| Month | <code>%m</code> | Number | 2 |
| | <code>%b</code> | Abbreviated name | Feb |
| | <code>%B</code> | Full name | February |
| Day | <code>%d</code> | Two digits | 02 |

| Type | Code | Meaning | Example |
|-------|------|--------------------------------|-----------------|
| | %e | One or two digits | 2 |
| Time | %H | 24-hour hour | 13 |
| | %I | 12-hour hour | 1 |
| | %p | AM/PM | pm |
| | %M | Minutes | 35 |
| | %S | Seconds | 45 |
| | %OS | Seconds with decimal component | 45.35 |
| | %Z | Time zone name | America/Chicago |
| | %z | Offset from UTC | +0800 |
| Other | %. . | Skip one non-digit | : |
| | %* | Skip any number of non-digits | |

And this code shows some a few options applied to a very ambiguous date:

```
csv <- "
  date
  01/02/15
"
read_csv(csv, col_types = cols(date = col_date("%m/%d/%y"))
#> # A tibble: 1 × 1
#>   date
#>   <date>
```

```
#> 1 2015-01-02

read_csv(csv, col_types = cols(date = col_date("%d/%m/%y"))
#> # A tibble: 1 × 1
#>   date
#>   <date>
#> 1 2015-02-01

read_csv(csv, col_types = cols(date = col_date("%y/%m/%d"))
#> # A tibble: 1 × 1
#>   date
#>   <date>
#> 1 2001-02-15
```

Note that no matter how you specify the date format, it's always displayed the same way once you get it into R.

If you're using `%b` or `%B` and working with non-English dates, you'll also need to provide a `locale()`. See the list of built-in languages in `date_names_langs()`, or create your own with `date_names()`,

19.2.2 From strings

The date-time specification language is powerful, but requires careful analysis of the date format. An alternative approach is to use lubridate's helpers which attempt to automatically determine the format once you specify the order of the component. To use them, identify the order in which year, month, and day appear in your dates, then arrange "y", "m", and "d" in the same order. That gives you the name of the lubridate function that will parse your date. For example:

```
ymd("2017-01-31")
#> [1] "2017-01-31"
mdy("January 31st, 2017")
```

```
#> [1] "2017-01-31"  
dmy("31-Jan-2017")  
#> [1] "2017-01-31"
```

`ymd()` and friends create dates. To create a date-time, add an underscore and one or more of “h”, “m”, and “s” to the name of the parsing function:

```
ymd_hms("2017-01-31 20:11:59")  
#> [1] "2017-01-31 20:11:59 UTC"  
mdy_hm("01/31/2017 08:01")  
#> [1] "2017-01-31 08:01:00 UTC"
```

You can also force the creation of a date-time from a date by supplying a timezone:

```
ymd("2017-01-31", tz = "UTC")  
#> [1] "2017-01-31 UTC"
```

19.2.3 From individual components

Instead of a single string, sometimes you’ll have the individual components of the date-time spread across multiple columns. This is what we have in the `flights` data:

```
flights |>  
  select(year, month, day, hour, minute)  
#> # A tibble: 336,776 × 5  
#>   year   month   day   hour   minute  
#>   <int> <int> <int> <dbl>   <dbl>  
#> 1 2013     1     1     5     15  
#> 2 2013     1     1     5     29  
#> 3 2013     1     1     5     40  
#> 4 2013     1     1     5     45  
#> 5 2013     1     1      6      0
```

```
#> 6 2013     1     1     5     58  
#> # ... with 336,770 more rows
```

To create a date/time from this sort of input, use `make_date()` for dates, or `make_datetime()` for date-times:

```
flights |>  
  select(year, month, day, hour, minute) |>  
  mutate(departure = make_datetime(year, month, day, hour, minute))  
#> # A tibble: 336,776 × 6  
#>   year month   day hour minute departure  
#>   <int> <int> <int> <dbl> <dbl> <dttm>  
#> 1 2013     1     1     5     15 2013-01-01 05:15:00  
#> 2 2013     1     1     5     29 2013-01-01 05:29:00  
#> 3 2013     1     1     5     40 2013-01-01 05:40:00  
#> 4 2013     1     1     5     45 2013-01-01 05:45:00  
#> 5 2013     1     1     6      0 2013-01-01 06:00:00  
#> 6 2013     1     1     5     58 2013-01-01 05:58:00  
#> # ... with 336,770 more rows
```

Let's do the same thing for each of the four time columns in `flights`. The times are represented in a slightly odd format, so we use modulus arithmetic to pull out the hour and minute components. Once we've created the date-time variables, we focus in on the variables we'll explore in the rest of the chapter.

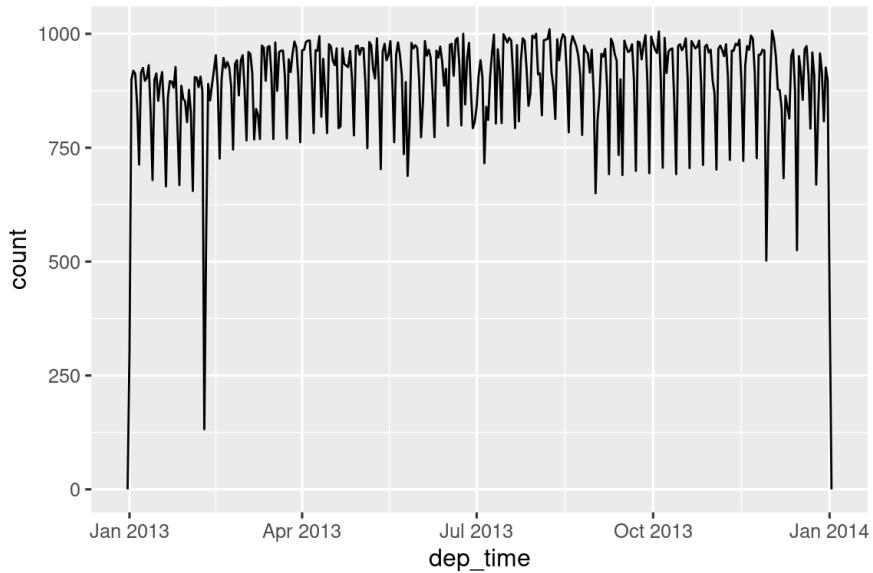

```
make_datetime_100 <- function(year, month, day, time) {  
  make_datetime(year, month, day, time %% 100, time %%% 100)  
}  
  
flights_dt <- flights |>  
  filter(!is.na(dep_time), !is.na(arr_time)) |>  
  mutate(  
    dep_time = make_datetime_100(year, month, day, dep_time),  
    arr_time = make_datetime_100(year, month, day, arr_time)
```

```
arr_time = make_datetime_100(year, month, day, arr_t
sched_dep_time = make_datetime_100(year, month, day,
sched_arr_time = make_datetime_100(year, month, day,
) |>
select(origin, dest, ends_with("delay"), ends_with("ti

flights_dt
#> # A tibble: 328,063 × 9
#>   origin dest  dep_delay arr_delay dep_time
#>   <chr>  <chr>     <dbl>     <dbl> <dttm>
#> 1 EWR    IAH        2         11 2013-01-01 05:17:0
#> 2 LGA    IAH        4         20 2013-01-01 05:33:0
#> 3 JFK    MIA        2         33 2013-01-01 05:42:0
#> 4 JFK    BQN       -1        -18 2013-01-01 05:44:0
#> 5 LGA    ATL       -6        -25 2013-01-01 05:54:0
#> 6 EWR    ORD       -4        12 2013-01-01 05:54:0
#> # ... with 328,057 more rows, and 3 more variables: arr
#> #   sched_arr_time <dttm>, air_time <dbl>
```

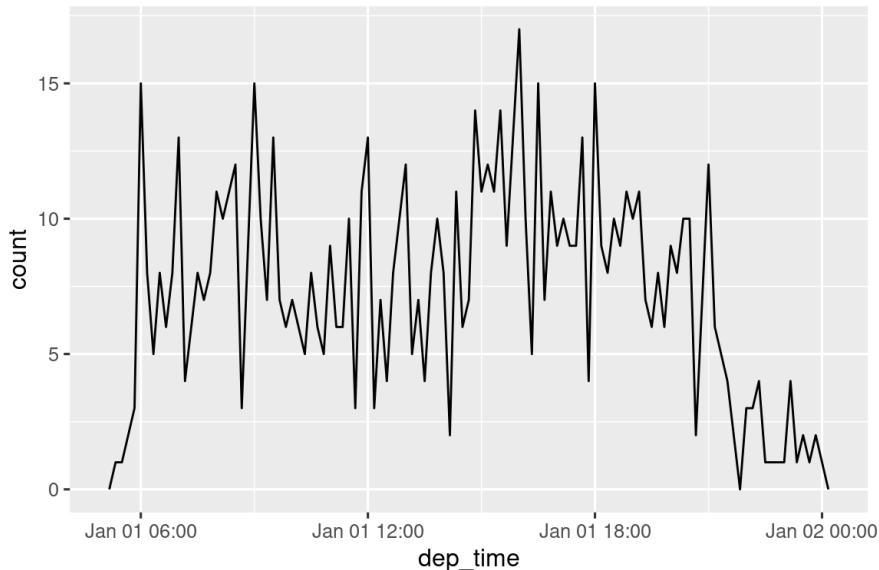

With this data, we can visualize the distribution of departure times across the year:

```
flights_dt |>
ggplot(aes(x = dep_time)) +
geom_freqpoly(binwidth = 86400) # 86400 seconds = 1 day
```

Or within a single day:

```
flights_dt |>  
  filter(dep_time < ymd("20130102")) |>  
  ggplot(aes(x = dep_time)) +  
  geom_freqpoly(binwidth = 600) # 600 s = 10 minutes
```

Note that when you use date-times in a numeric context (like in a histogram), 1 means 1 second, so a binwidth of 86400 means one day. For dates, 1 means 1 day.

19.2.4 From other types

You may want to switch between a date-time and a date. That's the job of `as_datetime()` and `as_date()`:

```
as_datetime(today())
#> [1] "2023-01-19 UTC"
as_date(now())
#> [1] "2023-01-19"
```

Sometimes you'll get date/times as numeric offsets from the “Unix Epoch”, 1970-01-01. If the offset is in seconds, use `as_datetime()`; if it's in days, use `as_date()`.

```
as_datetime(60 * 60 * 10)
#> [1] "1970-01-01 10:00:00 UTC"
as_date(365 * 10 + 2)
#> [1] "1980-01-01"
```

19.2.5 Exercises

1. What happens if you parse a string that contains invalid dates?

```
ymd(c("2010-10-10", "bananas"))
```

2. What does the `tzone` argument to `today()` do? Why is it important?
3. For each of the following date-times show how you'd parse it using a `readr` column-specification and a `lubridate` function.

```
d1 <- "January 1, 2010"
d2 <- "2015-Mar-07"
d3 <- "06-Jun-2017"
d4 <- c("August 19 (2015)", "July 1 (2015)")
d5 <- "12/30/14" # Dec 30, 2014
t1 <- "1705"
t2 <- "11:15:10.12 PM"
```

19.3 Date-time components

Now that you know how to get date-time data into R's date-time data structures, let's explore what you can do with them. This section will focus on the accessor functions that let you get and set individual components. The next section will look at how arithmetic works with date-times.

19.3.1 Getting components

You can pull out individual parts of the date with the accessor functions

`year()`, `month()`, `mday()` (day of the month), `yday()` (day of the year), `wday()` (day of the week), `hour()`, `minute()`, and `second()`.

```
datetime <- ymd_hms("2026-07-08 12:34:56")

year(datetime)
#> [1] 2026
month(datetime)
#> [1] 7
mday(datetime)
#> [1] 8

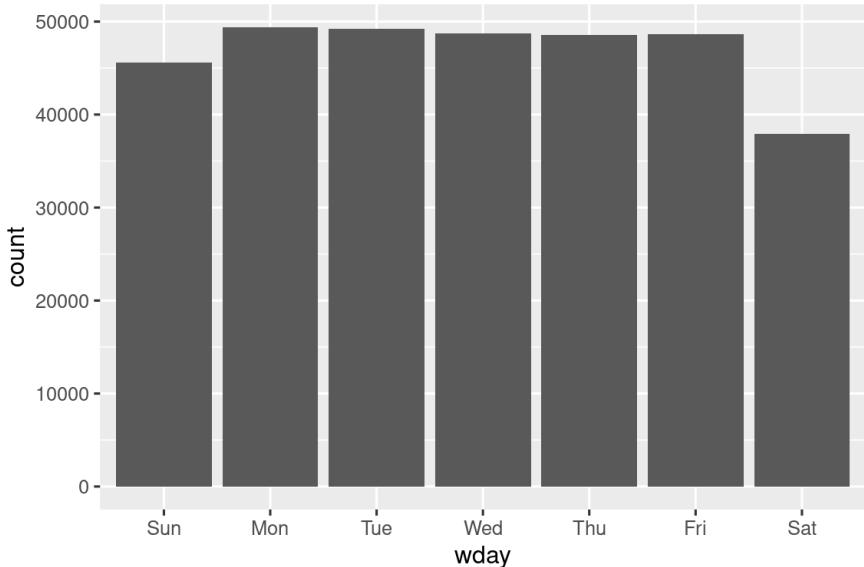

yday(datetime)
#> [1] 189
wday(datetime)
#> [1] 4
```

For `month()` and `wday()` you can set `label = TRUE` to return the abbreviated name of the month or day of the week. Set `abbr = FALSE` to return the full name.

```
month(datetime, label = TRUE)
#> [1] Jul
#> 12 Levels: Jan < Feb < Mar < Apr < May < Jun < Jul <
wday(datetime, label = TRUE, abbr = FALSE)
#> [1] Wednesday
#> 7 Levels: Sunday < Monday < Tuesday < Wednesday < Thu
```

We can use `wday()` to see that more flights depart during the week than on the weekend:

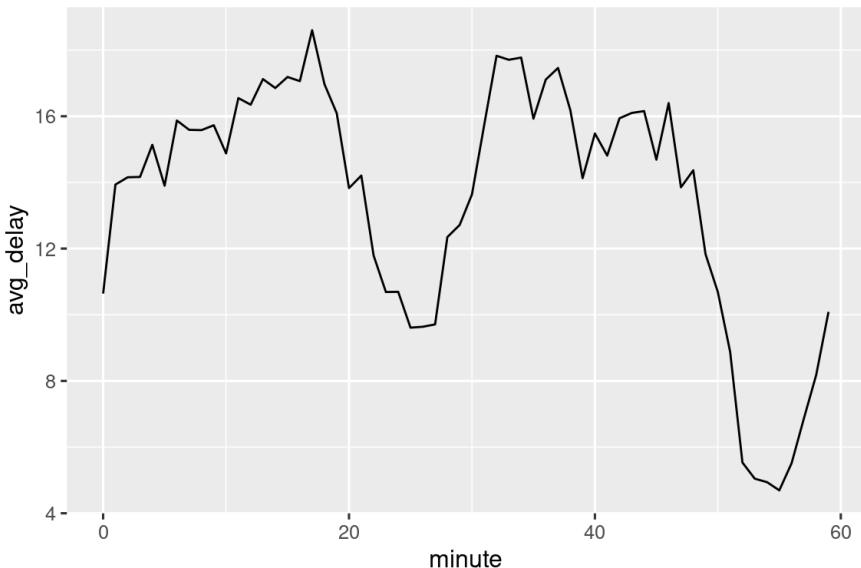

```
flights_dt |>  
  mutate(wday = wday(dep_time, label = TRUE)) |>  
  ggplot(aes(x = wday)) +  
  geom_bar()
```

There's an interesting pattern if we look at the average departure delay by minute within the hour. It looks like flights leaving in minutes 20-30 and 50-60 have much lower delays than the rest of the hour!

```
flights_dt |>  
  mutate(minute = minute(dep_time)) |>  
  group_by(minute) |>  
  summarize(  
    avg_delay = mean(dep_delay, na.rm = TRUE),  
    n = n()  
  ) |>
```

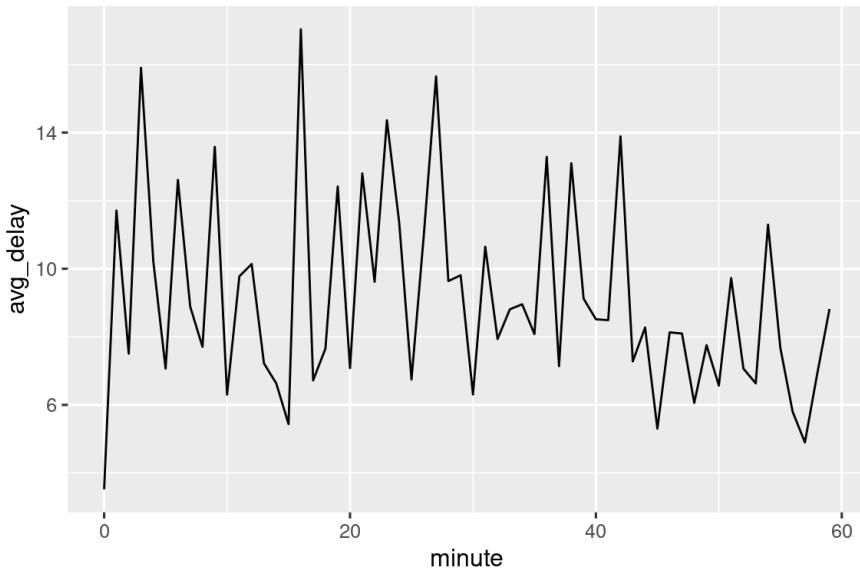

```
ggplot(aes(x = minute, y = avg_delay)) +  
  geom_line()
```

Interestingly, if we look at the *scheduled* departure time we don't see such a strong pattern:

```
sched_dep <- flights_dt |>  
  mutate(minute = minute(sched_dep_time)) |>  
  group_by(minute) |>  
  summarize(  
    avg_delay = mean(arr_delay, na.rm = TRUE),  
    n = n()  
)
```

```
ggplot(sched_dep, aes(x = minute, y = avg_delay)) +  
  geom_line()
```

So why do we see that pattern with the actual departure times? Well, like much data collected by humans, there's a strong bias towards flights leaving at "nice" departure times, as [Figure 19.1](#) shows. Always be alert for this sort of pattern whenever you work with data that involves human judgement!

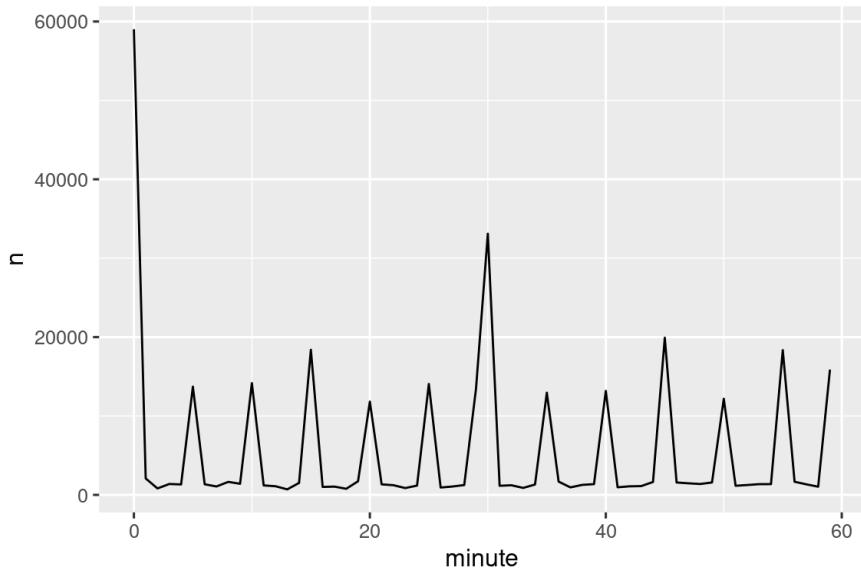

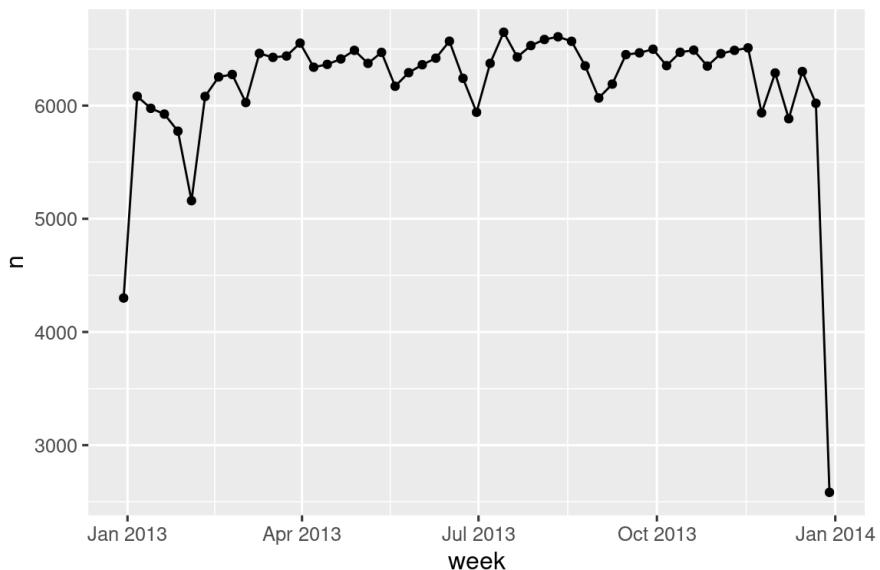

Figure 19.1: A frequency polygon showing the number of flights scheduled to depart each hour. You can see a strong preference for round numbers like 0 and 30 and generally for numbers that are a multiple of five.

19.3.2 Rounding

An alternative approach to plotting individual components is to round the date to a nearby unit of time, with `floor_date()`, `round_date()`, and `ceiling_date()`. Each function takes a vector of dates to adjust and then the name of the unit round down (floor), round up (ceiling), or round to. This, for example, allows us to plot the number of flights per week:

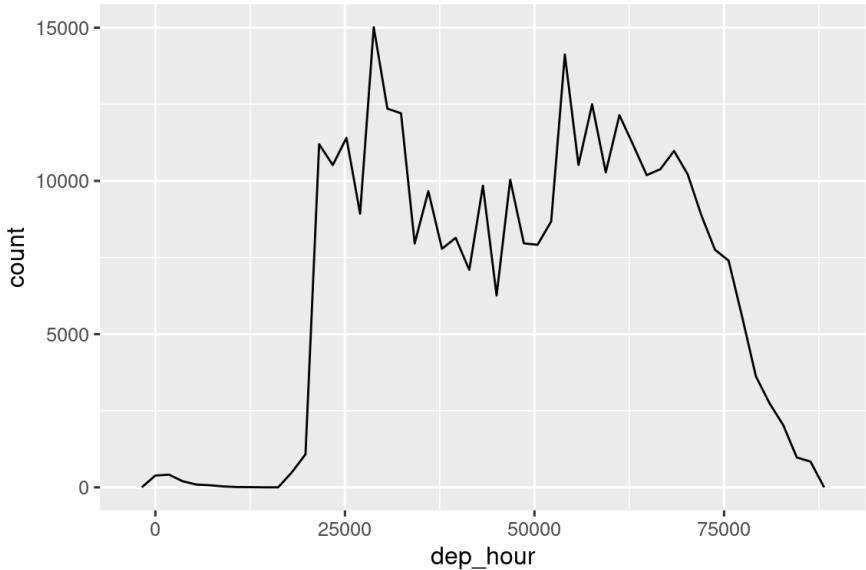

```
flights_dt |>
  count(week = floor_date(dep_time, "week")) |>
  ggplot(aes(x = week, y = n)) +
```

```
geom_line() +  
geom_point()
```

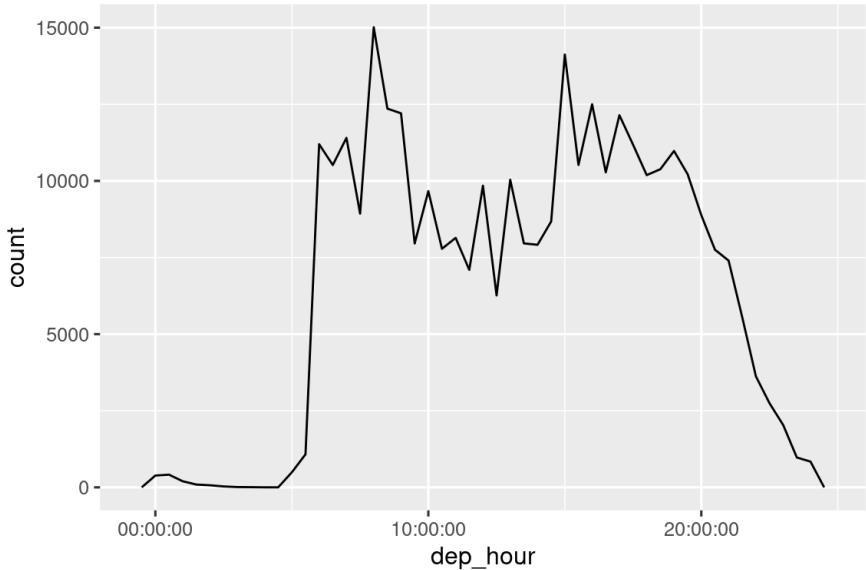

You can use rounding to show the distribution of flights across the course of a day by computing the difference between `dep_time` and the earliest instant of that day:

```
flights_dt |>  
  mutate(dep_hour = dep_time - floor_date(dep_time, "day")) +  
  ggplot(aes(x = dep_hour)) +  
  geom_freqpoly(binwidth = 60 * 30)  
#> Don't know how to automatically pick scale for object  
#> Defaulting to continuous.
```

Computing the difference between a pair of date-times yields a difftime (more on that in [Section 19.4.3](#)). We can convert that to an `hms` object to get a more useful x-axis:

```
flights_dt |>  
  mutate(dep_hour = hms::as_hms(dep_time - floor_date(deptime))) +  
  ggplot(aes(x = dep_hour)) +  
  geom_freqpoly(binwidth = 60 * 30)
```

19.3.3 Modifying components

You can also use each accessor function to modify the components of a date/time. This doesn't come up much in data analysis, but can be useful when cleaning data that has clearly incorrect dates.

```
(datetime <- ymd_hms("2026-07-08 12:34:56"))
#> [1] "2026-07-08 12:34:56 UTC"

year(datetime) <- 2030
datetime
#> [1] "2030-07-08 12:34:56 UTC"
month(datetime) <- 01
datetime
#> [1] "2030-01-08 12:34:56 UTC"
hour(datetime) <- hour(datetime) + 1
datetime
#> [1] "2030-01-08 13:34:56 UTC"
```

Alternatively, rather than modifying an existing variable, you can create a new date-time with `update()`. This also allows you to set multiple values in one step:

```
update(datetime, year = 2030, month = 2, mday = 2, hour  
#> [1] "2030-02-02 02:34:56 UTC"
```

If values are too big, they will roll-over:

```
update(ymd("2023-02-01"), mday = 30)  
#> [1] "2023-03-02"  
update(ymd("2023-02-01"), hour = 400)  
#> [1] "2023-02-17 16:00:00 UTC"
```

19.3.4 Exercises

1. How does the distribution of flight times within a day change over the course of the year?
2. Compare `dep_time`, `sched_dep_time` and `dep_delay`. Are they consistent? Explain your findings.
3. Compare `air_time` with the duration between the departure and arrival. Explain your findings. (Hint: consider the location of the airport.)
4. How does the average delay time change over the course of a day? Should you use `dep_time` or `sched_dep_time`? Why?
5. On what day of the week should you leave if you want to minimise the chance of a delay?

6. What makes the distribution of `diamonds$carat` and `flights$sched_dep_time` similar?
7. Confirm our hypothesis that the early departures of flights in minutes 20-30 and 50-60 are caused by scheduled flights that leave early. Hint: create a binary variable that tells you whether or not a flight was delayed.

19.4 Time spans

Next you'll learn about how arithmetic with dates works, including subtraction, addition, and division. Along the way, you'll learn about three important classes that represent time spans:

- **Durations**, which represent an exact number of seconds.
- **Periods**, which represent human units like weeks and months.
- **Intervals**, which represent a starting and ending point.

How do you pick between duration, periods, and intervals? As always, pick the simplest data structure that solves your problem. If you only care about physical time, use a duration; if you need to add human times, use a period; if you need to figure out how long a span is in human units, use an interval.

19.4.1 Durations

In R, when you subtract two dates, you get a `difftime` object:

```
# How old is Hadley?  
h_age <- today() - ymd("1979-10-14")  
h_age  
#> Time difference of 15803 days
```

A difftime class object records a time span of seconds, minutes, hours, days, or weeks. This ambiguity can make difftimes a little painful to work with, so lubridate provides an alternative which always uses seconds: the **duration**.

```
as.duration(h_age)
#> [1] "1365379200s (~43.27 years)"
```

Durations come with a bunch of convenient constructors:

```
dseconds(15)
#> [1] "15s"
dminutes(10)
#> [1] "600s (~10 minutes)"
dhours(c(12, 24))
#> [1] "43200s (~12 hours)" "86400s (~1 days)"
ddays(0:5)
#> [1] "0s"                      "86400s (~1 days)" "172800s"
#> [4] "259200s (~3 days)" "345600s (~4 days)" "432000s"
dweeks(3)
#> [1] "1814400s (~3 weeks)"
dyears(1)
#> [1] "31557600s (~1 years)"
```

Durations always record the time span in seconds. Larger units are created by converting minutes, hours, days, weeks, and years to seconds: 60 seconds in a minute, 60 minutes in an hour, 24 hours in a day, and 7 days in a week. Larger time units are more problematic. A year is uses the “average” number of days in a year, i.e. 365.25. There’s no way to convert a month to a duration, because there’s just too much variation.

You can add and multiply durations:

```
2 * dyears(1)
#> [1] "63115200s (~2 years)"
dyears(1) + dweeks(12) + dhours(15)
#> [1] "38869200s (~1.23 years)"
```

You can add and subtract durations to and from days:

```
tomorrow <- today() + ddays(1)
last_year <- today() - dyears(1)
```

However, because durations represent an exact number of seconds, sometimes you might get an unexpected result:

```
one_pm <- ymd_hms("2026-03-12 13:00:00", tz = "America/New_York")
one_pm
#> [1] "2026-03-12 13:00:00 EDT"
one_pm + ddays(1)
#> [1] "2026-03-13 13:00:00 EDT"
```

Why is one day after 1pm March 12, 2pm March 13? If you look carefully at the date you might also notice that the time zones have changed. March 12 only has 23 hours because it's when DST starts, so if we add a full days worth of seconds we end up with a different time.

19.4.2 Periods

To solve this problem, lubridate provides **periods**. Periods are time spans but don't have a fixed length in seconds, instead they work with “human” times, like days and months. That allows them to work in a more intuitive way:

```
one_pm  
#> [1] "2026-03-12 13:00:00 EDT"  
one_pm + days(1)  
#> [1] "2026-03-13 13:00:00 EDT"
```

Like durations, periods can be created with a number of friendly constructor functions.

```
hours(c(12, 24))  
#> [1] "12H 0M 0S" "24H 0M 0S"  
days(7)  
#> [1] "7d 0H 0M 0S"  
months(1:6)  
#> [1] "1m 0d 0H 0M 0S" "2m 0d 0H 0M 0S" "3m 0d 0H 0M 0S"  
#> [5] "5m 0d 0H 0M 0S" "6m 0d 0H 0M 0S"
```

You can add and multiply periods:

```
10 * (months(6) + days(1))  
#> [1] "60m 10d 0H 0M 0S"  
days(50) + hours(25) + minutes(2)  
#> [1] "50d 25H 2M 0S"
```

And of course, add them to dates. Compared to durations, periods are more likely to do what you expect:

```
# A leap year  
ymd("2024-01-01") + dyears(1)  
#> [1] "2024-12-31 06:00:00 UTC"  
ymd("2024-01-01") + years(1)  
#> [1] "2025-01-01"
```

```
# Daylight Savings Time  
one_pm + ddays(1)  
#> [1] "2026-03-13 13:00:00 EDT"  
one_pm + days(1)  
#> [1] "2026-03-13 13:00:00 EDT"
```

Let's use periods to fix an oddity related to our flight dates. Some planes appear to have arrived at their destination *before* they departed from New York City.

```
flights_dt |>  
  filter(arr_time < dep_time)  
#> # A tibble: 10,640 × 9  
#>   origin dest  dep_delay arr_delay dep_time  
#>   <chr>   <chr>     <dbl>     <dbl> <dttm>  
#> 1 EWR     BQN        9       -4 2013-01-01 19:29:0  
#> 2 JFK     DFW       59        NA 2013-01-01 19:39:0  
#> 3 EWR     TPA       -2        9 2013-01-01 20:58:0  
#> 4 EWR     SJU       -6       -12 2013-01-01 21:02:0  
#> 5 EWR     SF0       11       -14 2013-01-01 21:08:0  
#> 6 LGA     FLL      -10       -2 2013-01-01 21:20:0  
#> # ... with 10,634 more rows, and 3 more variables: arr_  
#> #   sched_arr_time <dttm>, air_time <dbl>
```

These are overnight flights. We used the same date information for both the departure and the arrival times, but these flights arrived on the following day. We can fix this by adding `days(1)` to the arrival time of each overnight flight.

```
flights_dt <- flights_dt |>  
  mutate(  
    overnight = arr_time < dep_time,  
    arr_time = arr_time + days(if_else(overnight, 0, 1))
```

```
    sched_arr_time = sched_arr_time + days(overnight * 1
)
```

Now all of our flights obey the laws of physics.

```
flights_dt |>
  filter(overnight, arr_time < dep_time)
#> # A tibble: 10,640 × 10
#>   origin dest  dep_delay arr_delay dep_time
#>   <chr>  <chr>     <dbl>     <dbl> <dttm>
#> 1 EWR    BQN        9       -4 2013-01-01 19:29:0
#> 2 JFK    DFW       59       NA 2013-01-01 19:39:0
#> 3 EWR    TPA       -2        9 2013-01-01 20:58:0
#> 4 EWR    SJU       -6       -12 2013-01-01 21:02:0
#> 5 EWR    SFO       11      -14 2013-01-01 21:08:0
#> 6 LGA    FLL      -10       -2 2013-01-01 21:20:0
#> # ... with 10,634 more rows, and 4 more variables: arr_
#> #   sched_arr_time <dttm>, air_time <dbl>, overnight
```

19.4.3 Intervals

It's obvious what `dyears(1) / ddays(365)` should return: one, because durations are always represented by a number of seconds, and a duration of a year is defined as 365 days worth of seconds.

What should `years(1) / days(1)` return? Well, if the year was 2015 it should return 365, but if it was 2016, it should return 366! There's not quite enough information for lubridate to give a single clear answer. What it does instead is give an estimate:

```
years(1) / days(1)
#> [1] 365.25
```

If you want a more accurate measurement, you'll have to use an **interval**. An interval is a pair of starting and ending date times, or you can think of it as a duration with a starting point.

You can create an interval by writing `start %--% end`:

```
y2023 <- ymd("2023-01-01") %--% ymd("2024-01-01")
y2024 <- ymd("2024-01-01") %--% ymd("2025-01-01")
```

```
y2023
#> [1] 2023-01-01 UTC--2024-01-01 UTC
y2024
#> [1] 2024-01-01 UTC--2025-01-01 UTC
```

You could then divide it by `days()` to find out how many days fit in the year:

```
y2023 / days(1)
#> [1] 365
y2024 / days(1)
#> [1] 366
```

19.4.4 Exercises

1. Explain `days(overnight * 1)` to someone who has just started learning R. How does it work?
2. Create a vector of dates giving the first day of every month in 2015.
Create a vector of dates giving the first day of every month in the *current* year.
3. Write a function that given your birthday (as a date), returns how old you are in years.

4. Why can't `(today() %--% (today() + years(1))) / months(1)` work?

19.5 Time zones

Time zones are an enormously complicated topic because of their interaction with geopolitical entities. Fortunately we don't need to dig into all the details as they're not all important for data analysis, but there are a few challenges we'll need to tackle head on.

The first challenge is that everyday names of time zones tend to be ambiguous. For example, if you're American you're probably familiar with EST, or Eastern Standard Time. However, both Australia and Canada also have EST! To avoid confusion, R uses the international standard IANA time zones. These use a consistent naming scheme `{area}/{location}`, typically in the form `{continent}/{city}` or `{ocean}/{city}`. Examples include "America/New_York", "Europe/Paris", and "Pacific/Auckland".

You might wonder why the time zone uses a city, when typically you think of time zones as associated with a country or region within a country. This is because the IANA database has to record decades worth of time zone rules. Over the course of decades, countries change names (or break apart) fairly frequently, but city names tend to stay the same. Another problem is that the name needs to reflect not only the current behavior, but also the complete history. For example, there are time zones for both "America/New_York" and "America/Detroit". These cities both currently use Eastern Standard Time but in 1969-1972 Michigan (the state in which Detroit is located), did not follow DST, so it needs a different name. It's worth reading the raw time zone database (available at <https://www.iana.org/time-zones>) just to read some of these stories!

You can find out what R thinks your current time zone is with

`Sys.timezone()`:

```
Sys.timezone()
```

```
#> [1] "UTC"
```

(If R doesn't know, you'll get an `NA`.)

And see the complete list of all time zone names with `OlsonNames()`:

```
length(OlsonNames())
```

```
#> [1] 597
```

```
head(OlsonNames())
```

```
#> [1] "Africa/Abidjan"      "Africa/Accra"      "Africa/
```

```
#> [4] "Africa/Algiers"      "Africa/Asmara"     "Africa/
```

In R, the time zone is an attribute of the date-time that only controls printing. For example, these three objects represent the same instant in time:

```
x1 <- ymd_hms("2024-06-01 12:00:00", tz = "America/New_York")
```

```
x1
```

```
#> [1] "2024-06-01 12:00:00 EDT"
```

```
x2 <- ymd_hms("2024-06-01 18:00:00", tz = "Europe/Copenhagen")
```

```
x2
```

```
#> [1] "2024-06-01 18:00:00 CEST"
```

```
x3 <- ymd_hms("2024-06-02 04:00:00", tz = "Pacific/Auckland")
```

```
x3
```

```
#> [1] "2024-06-02 04:00:00 NZST"
```

You can verify that they're the same time using subtraction:

```
x1 - x2  
#> Time difference of 0 secs  
x1 - x3  
#> Time difference of 0 secs
```

Unless otherwise specified, lubridate always uses UTC. UTC (Coordinated Universal Time) is the standard time zone used by the scientific community and is roughly equivalent to GMT (Greenwich Mean Time). It does not have DST, which makes a convenient representation for computation. Operations that combine date-times, like `c()`, will often drop the time zone. In that case, the date-times will display in your local time zone:

```
x4 <- c(x1, x2, x3)  
x4  
#> [1] "2024-06-01 12:00:00 EDT" "2024-06-01 12:00:00 ED  
#> [3] "2024-06-01 12:00:00 EDT"
```

You can change the time zone in two ways:

- Keep the instant in time the same, and change how it's displayed. Use this when the instant is correct, but you want a more natural display.

```
x4a <- with_tz(x4, tzone = "Australia/Lord_Howe")  
x4a  
#> [1] "2024-06-02 02:30:00 +1030" "2024-06-02 02:30  
#> [3] "2024-06-02 02:30:00 +1030"  
x4a - x4
```

```
#> Time differences in secs  
#> [1] 0 0 0
```

(This also illustrates another challenge of times zones: they're not all integer hour offsets!)

- Change the underlying instant in time. Use this when you have an instant that has been labelled with the incorrect time zone, and you need to fix it.

```
x4b <- force_tz(x4, tzzone = "Australia/Lord_Howe")  
x4b  
#> [1] "2024-06-01 12:00:00 +1030" "2024-06-01 12:00:00 +1030"  
#> [3] "2024-06-01 12:00:00 +1030"  
x4b - x4  
#> Time differences in hours  
#> [1] -14.5 -14.5 -14.5
```

19.6 Summary

This chapter has introduced you to the tools that lubridate provides to help you work with date-time data. Working with dates and times can seem harder than necessary, but hopefully this chapter has helped you see why — date-times are more complex than they seem at first glance, and handling every possible situation adds complexity. Even if your data never crosses a day light savings boundary or involves a leap year, the functions need to be able to handle it.

The next chapter gives a round up of missing values. You've seen them in a few places and have no doubt encounter in your own analysis, and it's

how time to provide a grab bag of useful techniques for dealing with them.

1. A year is a leap year if it's divisible by 4, unless it's also divisible by 100, except if it's also divisible by 400. In other words, in every set of 400 years, there's 97 leap years.
2. <https://xkcd.com/1179/>

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

20.1 Introduction

You've already learned the basics of missing values earlier in the book. You first saw them in [Chapter 2](#) where they resulted in a warning when making a plot as well as in [Section 4.4.2](#) where they interfered with computing summary statistics, and you learned about their infectious nature and how to check for their presence in [Section 14.2.2](#). Now we'll come back to them in more depth, so you can learn more of the details.

We'll start by discussing some general tools for working with missing values recorded as `NA`s. We'll then explore the idea of implicitly missing values, values that are simply absent from your data, and show some tools you can use to make them explicit. We'll finish off with a related discussion of empty groups, caused by factor levels that don't appear in the data.

20.1.1 Prerequisites

The functions for working with missing data mostly come from `dplyr` and `tidyverse`, which are core members of the tidyverse.

```
library(tidyverse)
```

20.2 Explicit missing values

To begin, let's explore a few handy tools for creating or eliminating missing explicit values, i.e. cells where you see an `NA`.

20.2.1 Last observation carried forward

A common use for missing values is as a data entry convenience. When data is entered by hand, missing values sometimes indicate that the value in the previous row has been repeated (or carried forward):

```
treatment <- tribble(  
  ~person,           ~treatment, ~response,  
  "Derrick Whitmore", 1,          7,  
  NA,                2,          10,  
  NA,                3,          NA,  
  "Katherine Burke", 1,          4  
)
```

You can fill in these missing values with `tidy::fill()`. It works like `select()`, taking a set of columns:

```
treatment |>  
  fill(everything())  
#> # A tibble: 4 × 3  
#>   person      treatment response  
#>   <chr>       <dbl>     <dbl>  
#> 1 Derrick Whitmore      1        7  
#> 2 Derrick Whitmore      2       10  
#> 3 Derrick Whitmore      3       10  
#> 4 Katherine Burke      1        4
```

This treatment is sometimes called “last observation carried forward”, or **locf** for short. You can use the `.direction` argument to fill in missing values that have been generated in more exotic ways.

20.2.2 Fixed values

Sometimes missing values represent some fixed and known value, most commonly 0. You can use `dplyr::coalesce()` to replace them:

```
x <- c(1, 4, 5, 7, NA)
coalesce(x, 0)
#> [1] 1 4 5 7 0
```

Sometimes you’ll hit the opposite problem where some concrete value actually represents a missing value. This typically arises in data generated by older software that doesn’t have a proper way to represent missing values, so it must instead use some special value like 99 or -999.

If possible, handle this when reading in the data, for example, by using the `na` argument to `readr::read_csv()`. If you discover the problem later, or your data source doesn’t provide a way to handle on it read, you can use `dplyr::na_if()`:

```
x <- c(1, 4, 5, 7, -99)
na_if(x, -99)
#> [1] 1 4 5 7 NA
```

20.2.3 NaN

Before we continue, there’s one special type of missing value that you’ll encounter from time to time: a **NaN** (pronounced “nan”), or **not a number**. It’s not that important to know about because it generally behaves just like `NA`:

```
x <- c(NA, NaN)
x * 10
#> [1] NA NaN
x == 1
#> [1] NA NA
is.na(x)
#> [1] TRUE TRUE
```

In the rare case you need to distinguish an `NA` from a `NaN`, you can use `is.nan(x)`.

You'll generally encounter a `NaN` when you perform a mathematical operation that has an indeterminate result:

```
0 / 0
#> [1] NaN
0 * Inf
#> [1] NaN
Inf - Inf
#> [1] NaN
sqrt(-1)
#> Warning in sqrt(-1): NaNs produced
#> [1] NaN
```

20.3 Implicit missing values

So far we've talked about missing values that are **explicitly** missing, i.e. you can see an `NA` in your data. But missing values can also be **implicitly** missing, if an entire row of data is simply absent from the data. Let's illustrate the difference with a simple data set that records the price of some stock each quarter:

```
stocks <- tibble(  
  year = c(2020, 2020, 2020, 2020, 2021, 2021, 2021),  
  qtr = c(1, 2, 3, 4, 2, 3, 4),  
  price = c(1.88, 0.59, 0.35, NA, 0.92, 0.17, 2.66)  
)
```

This dataset has two missing observations:

- The `price` in the fourth quarter of 2020 is explicitly missing, because its value is `NA`.
- The `price` for the first quarter of 2021 is implicitly missing, because it simply does not appear in the dataset.

One way to think about the difference is with this Zen-like koan:

An explicit missing value is the presence of an absence.

An implicit missing value is the absence of a presence.

Sometimes you want to make implicit missings explicit in order to have something physical to work with. In other cases, explicit missings are forced upon you by the structure of the data and you want to get rid of them. The following sections discuss some tools for moving between implicit and explicit missingness.

20.3.1 Pivoting

You've already seen one tool that can make implicit missings explicit and vice versa: pivoting. Making data wider can make implicit missing values explicit because every combination of the rows and new columns must have some value. For example, if we pivot `stocks` to put the `quarter` in the columns, both missing values become explicit:

```
stocks |>
  pivot_wider(
    names_from = qtr,
    values_from = price
  )
#> # A tibble: 2 × 5
#>   year   `1`   `2`   `3`   `4`
#>   <dbl> <dbl> <dbl> <dbl> <dbl>
#> 1 2020   1.88  0.59  0.35 NA
#> 2 2021   NA     0.92  0.17  2.66
```

By default, making data longer preserves explicit missing values, but if they are structurally missing values that only exist because the data is not tidy, you can drop them (make them implicit) by setting `values_drop_na = TRUE`. See the examples in [Section 6.2](#) for more details.

20.3.2 Complete

`tidy::complete()` allows you to generate explicit missing values by providing a set of variables that define the combination of rows that should exist. For example, we know that all combinations of `year` and `qtr` should exist in the `stocks` data:

```
stocks |>
  complete(year, qtr)
#> # A tibble: 8 × 3
#>   year   qtr price
#>   <dbl> <dbl> <dbl>
#> 1 2020   1   1.88
#> 2 2020   2   0.59
#> 3 2020   3   0.35
#> 4 2020   4   NA
#> 5 2021   1   NA
```

```
#> 6 2021      2 0.92  
#> # ... with 2 more rows
```

Typically, you'll call `complete()` with names of existing variables, filling in the missing combinations. However, sometimes the individual variables are themselves incomplete, so you can instead provide your own data. For example, you might know that the `stocks` dataset is supposed to run from 2019 to 2021, so you could explicitly supply those values for `year`:

```
stocks |>  
  complete(year = 2019:2021, qtr)  
#> # A tibble: 12 × 3  
#>   year   qtr price  
#>   <dbl> <dbl> <dbl>  
#> 1 2019     1 NA  
#> 2 2019     2 NA  
#> 3 2019     3 NA  
#> 4 2019     4 NA  
#> 5 2020     1 1.88  
#> 6 2020     2 0.59  
#> # ... with 6 more rows
```

If the range of a variable is correct, but not all values are present, you could use `full_seq(x, 1)` to generate all values from `min(x)` to `max(x)` spaced out by 1.

In some cases, the complete set of observations can't be generated by a simple combination of variables. In that case, you can do manually what `complete()` does for you: create a data frame that contains all the rows that should exist (using whatever combination of techniques you need), then combine it with your original dataset with `dplyr::full_join()`.

20.3.3 Joins

This brings us to another important way of revealing implicitly missing observations: joins. You'll learn more about joins in [Chapter 21](#), but we wanted to quickly mention them to you here since you can often only know that values are missing from one dataset when you compare it another.

`dplyr::anti_join(x, y)` is a particularly useful tool here because it selects only the rows in `x` that don't have a match in `y`. For example, we can use two `anti_join()`s reveal to reveal that we're missing information for four airports and 722 planes mentioned in `flights`:

```
library(nycflights13)

flights |>
  distinct(faa = dest) |>
  anti_join(airports)
#> Joining with `by = join_by(faa)`
#> # A tibble: 4 × 1
#>   faa
#>   <chr>
#> 1 BQN
#> 2 SJU
#> 3 STT
#> 4 PSE

flights |>
  distinct(tailnum) |>
  anti_join(planes)
#> Joining with `by = join_by(tailnum)`
#> # A tibble: 722 × 1
#>   tailnum
#>   <chr>
#> 1 N3ALAA
#> 2 N3DUAA
#> 3 N542MQ
#> 4 N730MQ
```

```
#> 5 N9EAMQ  
#> 6 N532UA  
#> # ... with 716 more rows
```

20.3.4 Exercises

1. Can you find any relationship between the carrier and the rows that appear to be missing from `planes` ?

20.4 Factors and empty groups

A final type of missingness is the empty group, a group that doesn't contain any observations, which can arise when working with factors. For example, imagine we have a dataset that contains some health information about people:

```
health <- tibble(  
  name    = c("Ikaia", "Oletta", "Leriah", "Dashay", "Tre  
  smoker = factor(c("no", "no", "no", "no", "no"), level  
  age     = c(34L, 88L, 75L, 47L, 56L),  
)
```

And we want to count the number of smokers with `dplyr::count()`:

```
health |> count(smoker)  
#> # A tibble: 1 × 2  
#>   smoker     n  
#>   <fct>   <int>  
#> 1 no         5
```

This dataset only contains non-smokers, but we know that smokers exist; the group of non-smoker is empty. We can request `count()` to

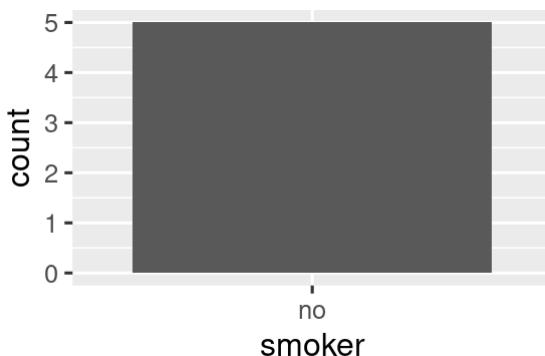

keep all the groups, even those not seen in the data by using `.drop = FALSE`:

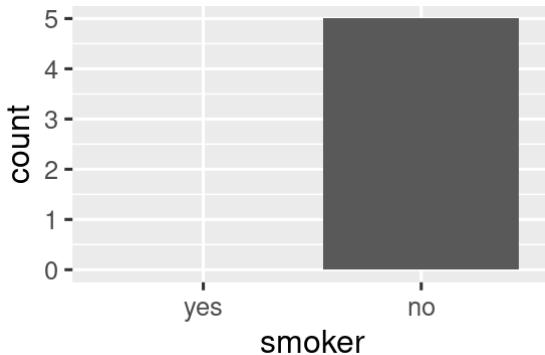

```
health |> count(smoker, .drop = FALSE)
#> # A tibble: 2 × 2
#>   smoker     n
#>   <fct>   <int>
#> 1 yes        0
#> 2 no         5
```

The same principle applies to ggplot2's discrete axes, which will also drop levels that don't have any values. You can force them to display by supplying `drop = FALSE` to the appropriate discrete axis:

```
ggplot(health, aes(x = smoker)) +
  geom_bar() +
  scale_x_discrete()

ggplot(health, aes(x = smoker)) +
  geom_bar() +
  scale_x_discrete(drop = FALSE)
```

The same problem comes up more generally with

`dplyr::group_by()`. And again you can use `.drop = FALSE` to preserve all factor levels:

```
health |>
  group_by(smoker, .drop = FALSE) |>
  summarize(
    n = n(),
    mean_age = mean(age),
    min_age = min(age),
    max_age = max(age),
    sd_age = sd(age)
  )
#> Warning: There were 2 warnings in `summarize()` .
#> The first warning was:
#> i In argument: `min_age = min(age)` .
#> i In group 1: `smoker = yes` .
#> Caused by warning in `min()` :
#> ! no non-missing arguments to min; returning Inf
#> i Run `dplyr::last_dplyr_warnings()` to see the 1 ren
#> # A tibble: 2 × 6
#>   smoker      n  mean_age  min_age  max_age  sd_age
#>   <fct>    <int>     <dbl>     <dbl>     <dbl>     <dbl>
```

```
#> 1 yes      0      NaN     Inf   -Inf    NA
#> 2 no       5      60      34     88    21.6
```

We get some interesting results here because when summarizing an empty group, the summary functions are applied to zero-length vectors. There's an important distinction between empty vectors, which have length 0, and missing values, each of which has length 1.

```
# A vector containing two missing values
x1 <- c(NA, NA)
length(x1)
#> [1] 2
```

```
# A vector containing nothing
x2 <- numeric()
length(x2)
#> [1] 0
```

All summary functions work with zero-length vectors, but they may return results that are surprising at first glance. Here we see `mean(age)` returning `NaN` because `mean(age) = sum(age)/length(age)` which here is $0/0$. `max()` and `min()` return `-Inf` and `Inf` for empty vectors so if you combine the results with a non-empty vector of new data and recompute you'll get the minimum or maximum of the new data¹.

Sometimes a simpler approach is to perform the summary and then make the implicit missings explicit with `complete()`.

```
health |>
  group_by(smoker) |>
  summarize(
    n = n(),
    mean_age = mean(age),
    min_age = min(age),
```

```
max_age = max(age),  
sd_age = sd(age)  
) |>  
complete(smoker)  
#> # A tibble: 2 × 6  
#>   smoker     n  mean_age  min_age  max_age  sd_age  
#>   <fct> <int>    <dbl>    <dbl>    <dbl>    <dbl>  
#> 1 yes      NA       NA       NA       NA       NA  
#> 2 no       5        60       34       88      21.6
```

The main drawback of this approach is that you get an `NA` for the count, even though you know that it should be zero.

20.5 Summary

Missing values are weird! Sometimes they're recorded as an explicit `NA` but other times you only notice them by their absence. This chapter has given you some tools for working with explicit missing values, tools for uncovering implicit missing values, and discussed some of the ways that implicit can become explicit and vice versa.

In the next chapter, we tackle the final chapter in this part of the book: joins. This is a bit of a change from the chapters so far because we're going to discuss tools that work with data frames as a whole, not something that you put inside a data frame.

1. In other words, `min(c(x, y))` is always equal to `min(min(x), min(y))`. 

i You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

21.1 Introduction

It's rare that a data analysis involves only a single data frame. Typically you have many data frames, and you must **join** them together to answer the questions that you're interested in. This chapter will introduce you to two important types of joins:

- Mutating joins, which add new variables to one data frame from matching observations in another.
- Filtering joins, which filter observations from one data frame based on whether or not they match an observation in another.

We'll begin by discussing keys, the variables used to connect a pair of data frames in a join. We cement the theory with an examination of the keys in the nycflights13 datasets, then use that knowledge to start joining data frames together. Next we'll discuss how joins work, focusing on their action on the rows. We'll finish up with a discussion of non-equi-joins, a family of joins that provide a more flexible way of matching keys than the default equality relationship.

21.1.1 Prerequisites

In this chapter, we'll explore the five related datasets from nycflights13 using the join functions from dplyr.

```
library(tidyverse)
library(nycflights13)
```

21.2 Keys

To understand joins, you need to first understand how two tables can be connected through a pair of keys, with one on each table. In this section, you'll learn about the two types of key and see examples of both in the datasets of the nycflights13 package. You'll also learn how to check that your keys are valid, and what to do if your table lacks a key.

21.2.1 Primary and foreign keys

Every join involves a pair of keys: a primary key and a foreign key. A **primary key** is a variable or set of variables that uniquely identifies each observation. When more than one variable is needed, the key is called a **compound key**. For example, in nycflights13:

- `airlines` records two pieces of data about each airline: its carrier code and its full name. You can identify an airline with its two letter carrier code, making `carrier` the primary key.

```
airlines
#> # A tibble: 16 × 2
#>   carrier name
#>   <chr>   <chr>
#> 1 9E      Endeavor Air Inc.
#> 2 AA      American Airlines Inc.
#> 3 AS      Alaska Airlines Inc.
#> 4 B6      JetBlue Airways
```

```
#> 5 DL      Delta Air Lines Inc.  
#> 6 EV      ExpressJet Airlines Inc.  
#> # ... with 10 more rows
```

- `airports` records data about each airport. You can identify each airport by its three letter airport code, making `faa` the primary key.

```
airports  
#> # A tibble: 1,458 × 8  
#>   faa     name          lat    lo  
#>   <chr>   <chr>        <dbl> <dbl>  
#> 1 04G    Lansdowne Airport  41.1 -80.  
#> 2 06A    Moton Field Municipal Airport 32.5 -85.  
#> 3 06C    Schaumburg Regional  42.0 -88.  
#> 4 06N    Randall Airport    41.4 -74.  
#> 5 09J    Jekyll Island Airport 31.1 -81.  
#> 6 0A9    Elizabethton Municipal Airport 36.4 -82.  
#> # ... with 1,452 more rows
```

- `planes` records data about each plane. You can identify a plane by its tail number, making `tailnum` the primary key.

```
planes  
#> # A tibble: 3,322 × 9  
#>   tailnum  year  type          manuf...¹ mode  
#>   <chr>    <int> <chr>        <chr>    <chr>  
#> 1 N10156  2004 Fixed wing multi en... EMBRAER EMB-  
#> 2 N102UW  1998 Fixed wing multi en... AIRBUS... A320  
#> 3 N103US  1999 Fixed wing multi en... AIRBUS... A320  
#> 4 N104UW  1999 Fixed wing multi en... AIRBUS... A320  
#> 5 N10575  2002 Fixed wing multi en... EMBRAER EMB-
```

```
#> 6 N105UW 1999 Fixed wing multi en... AIRBUS... A320
#> # ... with 3,316 more rows, and abbreviated variabl
```

- `weather` records data about the weather at the origin airports. You can identify each observation by the combination of location and time, making `origin` and `time_hour` the compound primary key.

`weather`

```
#> # A tibble: 26,115 × 15
#>   origin  year month   day hour  temp dewp humi
#>   <chr>   <int> <int> <int> <dbl> <dbl> <dbl>
#> 1 EWR     2013    1     1     1  39.0  26.1  59.
#> 2 EWR     2013    1     1     2  39.0  27.0  61.
#> 3 EWR     2013    1     1     3  39.0  28.0  64.
#> 4 EWR     2013    1     1     4  39.9  28.0  62.
#> 5 EWR     2013    1     1     5  39.0  28.0  64.
#> 6 EWR     2013    1     1     6  37.9  28.0  67.
#> # ... with 26,109 more rows, 4 more variables: prec
#> #   visib <dbl>, time_hour <dttm>, and abbreviate
#> #   1wind_speed, 2wind_gust
```

A **foreign key** is a variable (or set of variables) that corresponds to a primary key in another table. For example:

- `flights$tailnum` is a foreign key that corresponds to the primary key `planes$tailnum`.
- `flights$carrier` is a foreign key that corresponds to the primary key `airlines$carrier`.
- `flights$origin` is a foreign key that corresponds to the primary key `airports$faa`.
- `flights$dest` is a foreign key that corresponds to the primary key `airports$faa`.

- `flights$origin`-`flights$time_hour` is a compound foreign key that corresponds to the compound primary key `weather$origin`-`weather$time_hour`.

These relationships are summarized visually in [Figure 21.1](#).

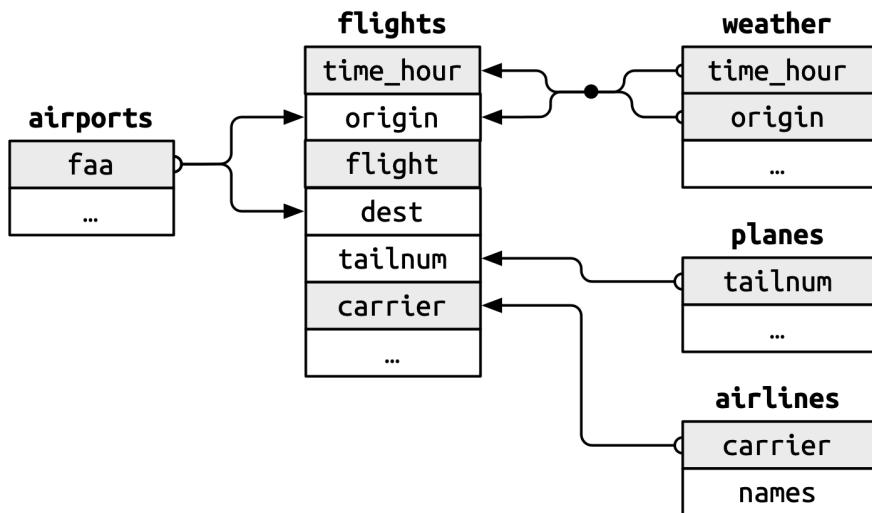

Figure 21.1: Connections between all five data frames in the `nycflights13` package. Variables making up a primary key are colored grey, and are connected to their corresponding foreign keys with arrows.

You'll notice a nice feature in the design of these keys: the primary and foreign keys almost always have the same names, which, as you'll see shortly, will make your joining life much easier. It's also worth noting the opposite relationship: almost every variable name used in multiple tables has the same meaning in each place. There's only one exception: `year` means year of departure in `flights` and year of manufacturer in `planes`. This will become important when we start actually joining tables together.

21.2.2 Checking primary keys

Now that we've identified the primary keys in each table, it's good practice to verify that they do indeed uniquely identify each observation. One way to do that is to `count()` the primary keys and look for entries where `n` is greater than one. This reveals that `planes` and `weather` both look good:

```
planes |>
  count(tailnum) |>
  filter(n > 1)
#> # A tibble: 0 × 2
#> # ... with 2 variables: tailnum <chr>, n <int>

weather |>
  count(time_hour, origin) |>
  filter(n > 1)
#> # A tibble: 0 × 3
#> # ... with 3 variables: time_hour <dttm>, origin <chr>,
```

You should also check for missing values in your primary keys — if a value is missing then it can't identify an observation!

```
planes |>
  filter(is.na(tailnum))
#> # A tibble: 0 × 9
#> # ... with 9 variables: tailnum <chr>, year <int>, type
#> #   manufacturer <chr>, model <chr>, engines <int>, s
#> #   speed <int>, engine <chr>

weather |>
  filter(is.na(time_hour) | is.na(origin))
#> # A tibble: 0 × 15
#> # ... with 15 variables: origin <chr>, year <int>, mont
#> #   hour <int>, temp <dbl>, dewp <dbl>, humid <dbl>,
```

```
#> #   wind_speed <dbl>, wind_gust <dbl>, precip <dbl>,
#> #   visib <dbl>, time_hour <dttm>
```

21.2.3 Surrogate keys

So far we haven't talked about the primary key for `flights`. It's not super important here, because there are no data frames that use it as a foreign key, but it's still useful to consider because it's easier to work with observations if have some way to describe them to others.

After a little thinking and experimentation, we determined that there are three variables that together uniquely identify each flight:

```
flights |>
  count(time_hour, carrier, flight) |>
  filter(n > 1)
#> # A tibble: 0 × 4
#> # ... with 4 variables: time_hour <dttm>, carrier <chr>
```

Does the absence of duplicates automatically make `time_hour-carrier-flight` a primary key? It's certainly a good start, but it doesn't guarantee it. For example, are altitude and latitude a good primary key for `airports`?

```
airports |>
  count(alt, lat) |>
  filter(n > 1)
#> # A tibble: 1 × 3
#>     alt    lat     n
#>   <dbl> <dbl> <int>
#> 1     13  40.6      2
```

Identifying an airport by its altitude and latitude is clearly a bad idea, and in general it's not possible to know from the data alone whether or not a combination of variables makes a good a primary key. But for flights, the combination of `time_hour`, `carrier`, and `flight` seems reasonable because it would be really confusing for an airline and its customers if there were multiple flights with the same flight number in the air at the same time.

That said, we might be better off introducing a simple numeric surrogate key using the row number:

```
flights2 <- flights |>
  mutate(id = row_number(), .before = 1)
flights2
#> # A tibble: 336,776 × 20
#>   id year month   day dep_time sched_de...¹ dep_d...²
#>   <int> <int> <int> <int>     <int>      <int>    <dbl>
#> 1 1 2013 1 1 517 515 2
#> 2 2 2013 1 1 533 529 4
#> 3 3 2013 1 1 542 540 2
#> 4 4 2013 1 1 544 545 -1
#> 5 5 2013 1 1 554 600 -6
#> 6 6 2013 1 1 554 558 -4
#> # ... with 336,770 more rows, 10 more variables: carrie
#> #   tailnum <chr>, origin <chr>, dest <chr>, air_time
#> #   hour <dbl>, minute <dbl>, time_hour <dttm>, and a
#> #   names ¹sched_dep_time, ²dep_delay, ³arr_time, ⁴sc
#> #   ⁵arr_delay
```

Surrogate keys can be particular useful when communicating to other humans: it's much easier to tell someone to take a look at flight 2001 than to say look at UA430 which departed 9am 2013-01-03.

21.2.4 Exercises

1. We forgot to draw the relationship between `weather` and `airports` in [Figure 21.1](#). What is the relationship and how should it appear in the diagram?
2. `weather` only contains information for the three origin airports in NYC. If it contained weather records for all airports in the USA, what additional connection would it make to `flights`?
3. The `year`, `month`, `day`, `hour`, and `origin` variables almost form a compound key for `weather`, but there's one hour that has duplicate observations. Can you figure out what's special about that hour?
4. We know that some days of the year are special and fewer people than usual fly on them (e.g. Christmas eve and Christmas day). How might you represent that data as a data frame? What would be the primary key? How would it connect to the existing data frames?
5. Draw a diagram illustrating the connections between the `Batting`, `People`, and `Salaries` data frames in the Lahman package. Draw another diagram that shows the relationship between `People`, `Managers`, `AwardsManagers`. How would you characterise the relationship between the `Batting`, `Pitching`, and `Fielding` data frames?

21.3 Basic joins

Now that you understand how data frames are connected via keys, we can start using joins to better understand the `flights` dataset. `dplyr` provides six join functions: `left_join()`, `inner_join()`,

`right_join()`, `semi_join()`, and `anti_join()`. They all have the same interface: they take a pair of data frames (`x` and `y`) and return a data frame. The order of the rows and columns in the output is primarily determined by `x`.

In this section, you'll learn how to use one mutating join, `left_join()`, and two filtering joins, `semi_join()` and `anti_join()`. In the next section, you'll learn exactly how these functions work, and about the remaining `inner_join()`, `right_join()` and `full_join()`.

21.3.1 Mutating joins

A **mutating join** allows you to combine variables from two data frames: it first matches observations by their keys, then copies across variables from one data frame to the other. Like `mutate()`, the join functions add variables to the right, so if your dataset has many variables, you won't see the new ones. For these examples, we'll make it easier to see what's going on by creating a narrower dataset with just six variables¹:

```
flights2 <- flights |>
  select(year, time_hour, origin, dest, tailnum, carrier)
flights2
#> # A tibble: 336,776 × 6
#>   year time_hour          origin  dest  tailnum  carr
#>   <int> <dttm>           <chr>   <chr> <chr>    <chr>
#> 1  2013 2013-01-01 05:00:00 EWR     IAH     N14228  UA
#> 2  2013 2013-01-01 05:00:00 LGA     IAH     N24211  UA
#> 3  2013 2013-01-01 05:00:00 JFK     MIA     N619AA  AA
#> 4  2013 2013-01-01 05:00:00 JFK     BQN     N804JB  B6
#> 5  2013 2013-01-01 06:00:00 LGA     ATL     N668DN  DL
#> 6  2013 2013-01-01 05:00:00 EWR     ORD     N39463  UA
#> # ... with 336,770 more rows
```

There are four types of mutating join, but there's one that you'll use almost all of the time: `left_join()`. It's special because the output will always have the same rows as `x`². The primary use of `left_join()` is to add in additional metadata. For example, we can use `left_join()` to add the full airline name to the `flights2` data:

```
flights2 |>
  left_join(airlines)
#> Joining with `by = join_by(carrier)`
#> # A tibble: 336,776 × 7
#>   year time_hour      origin dest tailnum carr
#>   <int> <dttm>       <chr>  <chr> <chr>  <chr>
#> 1 2013 2013-01-01 05:00:00 EWR     IAH    N14228  UA
#> 2 2013 2013-01-01 05:00:00 LGA     IAH    N24211  UA
#> 3 2013 2013-01-01 05:00:00 JFK     MIA    N619AA AA
#> 4 2013 2013-01-01 05:00:00 JFK     BQN    N804JB B6
#> 5 2013 2013-01-01 06:00:00 LGA     ATL    N668DN DL
#> 6 2013 2013-01-01 05:00:00 EWR     ORD    N39463 UA
#> # ... with 336,770 more rows
```

Or we could find out the temperature and wind speed when each plane departed:

```
flights2 |>
  left_join(weather |> select(origin, time_hour, temp, w
#> Joining with `by = join_by(time_hour, origin)`
#> # A tibble: 336,776 × 8
#>   year time_hour      origin dest tailnum carr
#>   <int> <dttm>       <chr>  <chr> <chr>  <chr>
#> 1 2013 2013-01-01 05:00:00 EWR     IAH    N14228  UA
#> 2 2013 2013-01-01 05:00:00 LGA     IAH    N24211  UA
#> 3 2013 2013-01-01 05:00:00 JFK     MIA    N619AA AA
#> 4 2013 2013-01-01 05:00:00 JFK     BQN    N804JB B6
#> 5 2013 2013-01-01 06:00:00 LGA     ATL    N668DN DL
```

```
#> 6 2013 2013-01-01 05:00:00 EWR      ORD      N39463  UA
#> # ... with 336,770 more rows
```

Or what size of plane was flying:

```
flights2 |>
  left_join(planes |> select(tailnum, type, engines, sea
#> Joining with `by = join_by(tailnum)`
#> # A tibble: 336,776 × 9
#>   year time_hour          origin dest tailnum carr
#>   <int> <dttm>           <chr>  <chr> <chr>  <chr>
#> 1 2013 2013-01-01 05:00:00 EWR    IAH    N14228  UA
#> 2 2013 2013-01-01 05:00:00 LGA    IAH    N24211  UA
#> 3 2013 2013-01-01 05:00:00 JFK    MIA    N619AA  AA
#> 4 2013 2013-01-01 05:00:00 JFK    BQN    N804JB  B6
#> 5 2013 2013-01-01 06:00:00 LGA    ATL    N668DN  DL
#> 6 2013 2013-01-01 05:00:00 EWR    ORD    N39463  UA
#> # ... with 336,770 more rows
```

When `left_join()` fails to find a match for a row in `x`, it fills in the new variables with missing values. For example, there's no information about the plane with tail number `N3ALAA` so the `type`, `engines`, and `seats` will be missing:

```
flights2 |>
  filter(tailnum == "N3ALAA") |>
  left_join(planes |> select(tailnum, type, engines, sea
#> Joining with `by = join_by(tailnum)`
#> # A tibble: 63 × 9
#>   year time_hour          origin dest tailnum carr
#>   <int> <dttm>           <chr>  <chr> <chr>  <chr>
#> 1 2013 2013-01-01 06:00:00 LGA    ORD    N3ALAA  AA
#> 2 2013 2013-01-02 18:00:00 LGA    ORD    N3ALAA  AA
```

```
#> 3 2013 2013-01-03 06:00:00 LGA      ORD    N3ALAA AA  
#> 4 2013 2013-01-07 19:00:00 LGA      ORD    N3ALAA AA  
#> 5 2013 2013-01-08 17:00:00 JFK      ORD    N3ALAA AA  
#> 6 2013 2013-01-16 06:00:00 LGA      ORD    N3ALAA AA  
#> # ... with 57 more rows
```

We'll come back to this problem a few times in the rest of the chapter.

21.3.2 Specifying join keys

By default, `left_join()` will use all variables that appear in both data frames as the join key, the so called **natural** join. This is a useful heuristic, but it doesn't always work. For example, what happens if we try to join `flights2` with the complete `planes` dataset?

```
flights2 |>  
  left_join(planes)  
#> Joining with `by = join_by(year, tailnum)`  
#> # A tibble: 336,776 × 13  
#>   year time_hour          origin dest  tailnum carr  
#>   <int> <dttm>           <chr>  <chr> <chr>  <chr>  
#> 1 2013 2013-01-01 05:00:00 EWR    IAH    N14228 UA  
#> 2 2013 2013-01-01 05:00:00 LGA    IAH    N24211 UA  
#> 3 2013 2013-01-01 05:00:00 JFK    MIA    N619AA AA  
#> 4 2013 2013-01-01 05:00:00 JFK    BQN    N804JB B6  
#> 5 2013 2013-01-01 06:00:00 LGA    ATL    N668DN DL  
#> 6 2013 2013-01-01 05:00:00 EWR    ORD    N39463 UA  
#> # ... with 336,770 more rows, 4 more variables: engines  
#> #   speed <int>, engine <chr>, and abbreviated variat
```

We get a lot of missing matches because our join is trying to use `tailnum` and `year` as a compound key. Both `flights` and `planes` have a `year` column but they mean different things: `flights$year` is

year the flight occurred and `planes$year` is the year the plane was built. We only want to join on `tailnum` so we need to provide an explicit specification with `join_by()`:

```
flights2 |>
  left_join(planes, join_by(tailnum))
#> # A tibble: 336,776 × 14
#>   year.x time_hour          origin dest tailnum car
#>   <int> <dttm>           <chr>  <chr> <chr>  <ch
#> 1 2013 2013-01-01 05:00:00 EWR     IAH    N14228  UA
#> 2 2013 2013-01-01 05:00:00 LGA     IAH    N24211  UA
#> 3 2013 2013-01-01 05:00:00 JFK     MIA    N619AA AA
#> 4 2013 2013-01-01 05:00:00 JFK     BQN    N804JB B6
#> 5 2013 2013-01-01 06:00:00 LGA     ATL    N668DN DL
#> 6 2013 2013-01-01 05:00:00 EWR     ORD    N39463 UA
#> # ... with 336,770 more rows, and 6 more variables: man
#> #   model <chr>, engines <int>, seats <int>, speed <i
```

Note that the `year` variables are disambiguated in the output with a suffix (`year.x` and `year.y`), which tells you whether the variable came from the `x` or `y` argument. You can override the default suffixes with the `suffix` argument.

`join_by(tailnum)` is short for `join_by(tailnum == tailnum)`. It's important to know about this fuller form for two reasons. Firstly, it describes the relationship between the two tables: the keys must be equal. That's why this type of join is often called an **equi-join**. You'll learn about non-equijoins in [Section 21.4.4](#).

Secondly, it's how you specify different join keys in each table. For example, there are two ways to join the `flight2` and `airports` table: either by `dest` or `origin`:

```
flights2 |>
  left_join(airports, join_by(dest == faa))
#> # A tibble: 336,776 × 13
#>   year time_hour      origin dest tailnum carr
#>   <int> <dttm>      <chr>  <chr> <chr>  <chr>
#> 1 2013 2013-01-01 05:00:00 EWR    IAH    N14228  UA
#> 2 2013 2013-01-01 05:00:00 LGA    IAH    N24211  UA
#> 3 2013 2013-01-01 05:00:00 JFK    MIA    N619AA  AA
#> 4 2013 2013-01-01 05:00:00 JFK    BQN    N804JB  B6
#> 5 2013 2013-01-01 06:00:00 LGA    ATL    N668DN  DL
#> 6 2013 2013-01-01 05:00:00 EWR    ORD    N39463  UA
#> # ... with 336,770 more rows, and 4 more variables: alt
#> #   dst <chr>, tzone <chr>
```

```
flights2 |>
  left_join(airports, join_by(origin == faa))
#> # A tibble: 336,776 × 13
#>   year time_hour      origin dest tailnum carr
#>   <int> <dttm>      <chr>  <chr> <chr>  <chr>
#> 1 2013 2013-01-01 05:00:00 EWR    IAH    N14228  UA
#> 2 2013 2013-01-01 05:00:00 LGA    IAH    N24211  UA
#> 3 2013 2013-01-01 05:00:00 JFK    MIA    N619AA  AA
#> 4 2013 2013-01-01 05:00:00 JFK    BQN    N804JB  B6
#> 5 2013 2013-01-01 06:00:00 LGA    ATL    N668DN  DL
#> 6 2013 2013-01-01 05:00:00 EWR    ORD    N39463  UA
#> # ... with 336,770 more rows, and 4 more variables: alt
#> #   dst <chr>, tzone <chr>
```

In older code you might see a different way of specifying the join keys, using a character vector:

- `by = "x"` corresponds to `join_by(x)`.
- `by = c("a" = "x")` corresponds to `join_by(a == x)`.

Now that it exists, we prefer `join_by()` since it provides a clearer and more flexible specification.

21.3.3 Filtering joins

As you might guess the primary action of a **filtering join** is to filter the rows. There are two types: semi-joins and anti-joins. **Semi-joins** keep all rows in `x` that have a match in `y`. For example, we could use a semi-join to filter the `airports` dataset to show just the origin airports:

```
airports |>
  semi_join(flights2, join_by(faa == origin))
#> # A tibble: 3 × 8
#>   faa     name           lat    lon    alt    tz  continent
#>   <chr>  <chr>        <dbl>  <dbl>  <dbl>  <dbl> <dbl>
#> 1 EWR    Newark Liberty Intl  40.7 -74.2   18    -5  A
#> 2 JFK    John F Kennedy Intl  40.6 -73.8   13    -5  A
#> 3 LGA    La Guardia        40.8 -73.9   22    -5  A
```

Or just the destinations:

```
airports |>
  semi_join(flights2, join_by(faa == dest))
#> # A tibble: 101 × 8
#>   faa     name           lat    lon  continent
#>   <chr>  <chr>        <dbl>  <dbl> <dbl>
#> 1 ABQ    Albuquerque International Sunpor... 35.0 -107.
#> 2 ACK    Nantucket Mem          41.3  -70.1
#> 3 ALB    Albany Intl           42.7  -73.8
#> 4 ANC    Ted Stevens Anchorage Intl      61.2 -150.
#> 5 ATL    Hartsfield Jackson Atlanta Intl  33.6  -84.4
```

```
#> 6 AUS Austin Bergstrom Intl          30.2 -97.7
#> # ... with 95 more rows
```

Anti-joins are the opposite: they return all rows in `x` that don't have a match in `y`. They're useful for finding missing values that are **implicit** in the data, the topic of [Section 20.3](#). Implicitly missing values don't show up as `NAs` but instead only exist as an absence. For example, we can find rows that are missing from `airports` by looking for flights that don't have a matching destination airport:

```
flights2 |>
  anti_join(airports, join_by(dest == faa)) |>
  distinct(dest)
#> # A tibble: 4 × 1
#>   dest
#>   <chr>
#> 1 BQN
#> 2 SJU
#> 3 STT
#> 4 PSE
```

Or we can find which `tailnums` are missing from `planes`:

```
flights2 |>
  anti_join(planes, join_by(tailnum)) |>
  distinct(tailnum)
#> # A tibble: 722 × 1
#>   tailnum
#>   <chr>
#> 1 N3ALAA
#> 2 N3DUAA
#> 3 N542MQ
#> 4 N730MQ
#> 5 N9EAMQ
```

```
#> 6 N532UA  
#> # ... with 716 more rows
```

21.3.4 Exercises

1. Find the 48 hours (over the course of the whole year) that have the worst delays. Cross-reference it with the `weather` data. Can you see any patterns?
2. Imagine you've found the top 10 most popular destinations using this code:

```
top_dest <- flights2 |>  
count(dest, sort = TRUE) |>  
head(10)
```

How can you find all flights to those destinations?

3. Does every departing flight have corresponding weather data for that hour?
4. What do the tail numbers that don't have a matching record in `planes` have in common? (Hint: one variable explains ~90% of the problems.)
5. Add a column to `planes` that lists every `carrier` that has flown that plane. You might expect that there's an implicit relationship between plane and airline, because each plane is flown by a single airline. Confirm or reject this hypothesis using the tools you've learned in previous chapters.
6. Add the latitude and the longitude of the origin *and* destination airport to `flights`. Is it easier to rename the columns before or after the join?

7. Compute the average delay by destination, then join on the `airports` data frame so you can show the spatial distribution of delays. Here's an easy way to draw a map of the United States:

```
airports |>
  semi_join(flights, join_by(faa == dest)) |>
  ggplot(aes(x = lon, y = lat)) +
  borders("state") +
  geom_point() +
  coord_quickmap()
```

You might want to use the `size` or `color` of the points to display the average delay for each airport.

8. What happened on June 13 2013? Draw a map of the delays, and then use Google to cross-reference with the weather.

21.4 How do joins work?

Now that you've used joins a few times it's time to learn more about how they work, focusing on how each row in `x` matches rows in `y`. We'll begin by using [Figure 21.2](#) to introduce a visual representation of the two simple tibbles defined below. In these examples we'll use a single key called `key` and a single value column (`val_x` and `val_y`), but the ideas all generalize to multiple keys and multiple values.

```
x <- tribble(
  ~key, ~val_x,
  1, "x1",
  2, "x2",
  3, "x3"
)
y <- tribble(
  ~key, ~val_y,
```

```

1, "y1",
2, "y2",
4, "y3"
)

```

| | x | y |
|---|----|----|
| 1 | x1 | y1 |
| 2 | x2 | y2 |
| 3 | x3 | y3 |

Figure 21.2: Graphical representation of two simple tables. The colored key columns map background color to key value. The grey columns represent the “value” columns that are carried along for the ride.

[Figure 21.3](#) shows all potential matches between `x` and `y` as the intersection between lines drawn from each row of `x` and each row of `y`. The rows and columns in the output are primarily determined by `x`, so the `x` table is horizontal and lines up with the output.

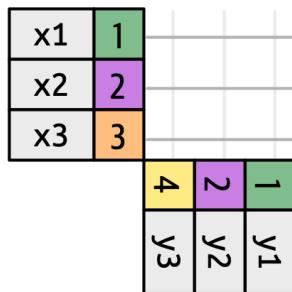

Figure 21.3: To understand how joins work, it’s useful to think of every possible match. Here we show that with a grid of connecting lines.

In an actual join, matches will be indicated with dots, as in [Figure 21.4](#). The number of dots equals the number of matches, which in turn equals the number of rows in the output, a new data frame that contains the

key, the `x` values, and the `y` values. The join shown here is a so-called **equi inner join**, where rows match if the keys are equal, so that the output contains only the rows with keys that appear in both `x` and `y`. Equi-joins are the most common type of join, so we'll typically omit the equi prefix, and just call it an inner join. We'll come back to non-equijoins in [Section 21.4.4](#).

`inner_join(x, y)`

| | | |
|----|----|----|
| x1 | 1 | |
| x2 | 2 | |
| x3 | 3 | |
| | 4 | 1 |
| | 2 | y2 |
| | y3 | y1 |

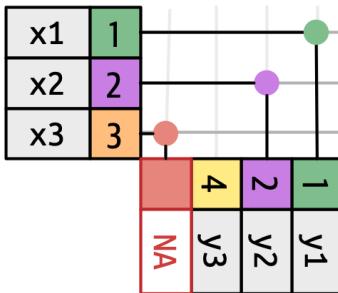

| key | val_x | val_y |
|-----|-------|-------|
| 1 | x1 | y1 |
| 2 | x2 | y2 |

Figure 21.4: An inner join matches each row in `x` to the row in `y` that has the same value of `key`. Each match becomes a row in the output.

An **outer join** keeps observations that appear in at least one of the data frames. These joins work by adding an additional “virtual” observation to each data frame. This observation has a key that matches if no other key matches, and values filled with `NA`. There are three types of outer joins:

- A **left join** keeps all observations in `x`, [Figure 21.5](#). Every row of `x` is preserved in the output because it can fall back to matching a row of `NAs` in `y`.

`left_join(x, y)`

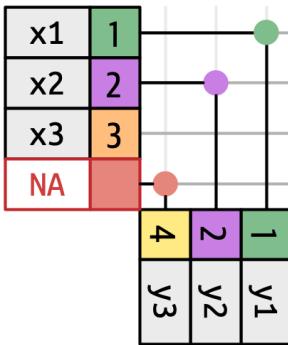

| key | val_x | val_y |
|-----|-------|-------|
| 1 | x1 | y1 |
| 2 | x2 | y2 |
| 3 | x3 | NA |

Figure 21.5: A visual representation of the left join where every row in `x` appears in the output.

- A **right join** keeps all observations in `y`, [Figure 21.6](#). Every row of `y` is preserved in the output because it can fall back to matching a row of `NAs` in `x`. The output still matches `x` as much as possible; any extra rows from `y` are added to the end.

`right_join(x, y)`

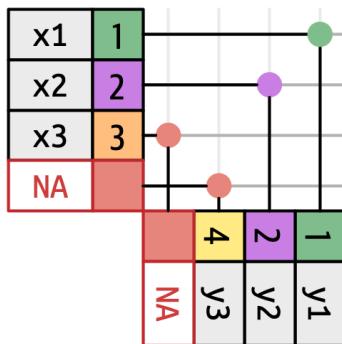

| key | val_x | val_y |
|-----|-------|-------|
| 1 | x1 | y1 |
| 2 | x2 | y2 |
| 4 | NA | y3 |

Figure 21.6: A visual representation of the right join where every row of `y` appears in the output.

- A **full join** keeps all observations that appear in `x` or `y`,

Figure 21.7. Every row of `x` and `y` is included in the output because both `x` and `y` have a fall back row of `NA`s. Again, the output starts with all rows from `x`, followed by the remaining unmatched `y` rows.

`full_join(x, y)`

| key | val_x | val_y |
|-----|-------|-------|
| 1 | x1 | y1 |
| 2 | x2 | y2 |
| 3 | x3 | NA |
| 4 | NA | y3 |

Figure 21.7: A visual representation of the full join where every row in `x` and `y` appears in the output.

Another way to show how the types of outer join differ is with a Venn diagram, as in Figure 21.8. However, this is not a great representation because while it might jog your memory about which rows are preserved, it fails to illustrate what's happening with the columns.

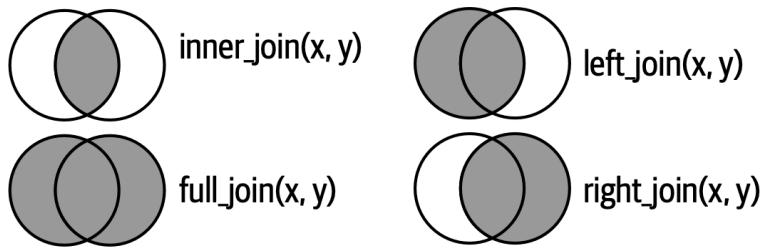

Figure 21.8: Venn diagrams showing the difference between inner, left, right, and full joins.

21.4.1 Row matching

So far we've explored what happens if a row in `x` matches zero or one rows in `y`. What happens if it matches more than one row? To understand what's going let's first narrow our focus to the `inner_join()` and then draw a picture, [Figure 21.9](#).

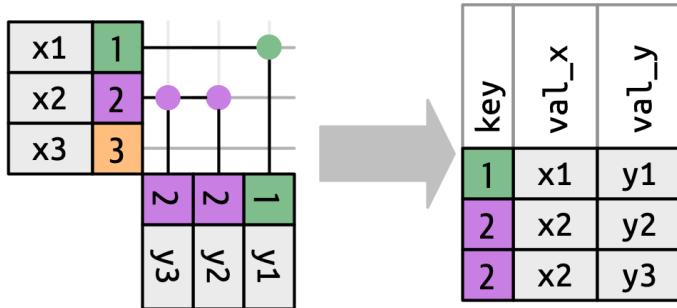

Figure 21.9: The three ways a row in `x` can match. `x1` matches one row in `y`, `x2` matches two rows in `y`, `x3` matches zero rows in `y`. Note that while there are three rows in `x` and three rows in the output, there isn't a direct correspondence between the rows.

There are three possible outcomes for a row in `x`:

- If it doesn't match anything, it's dropped.

- If it matches 1 row in `y`, it's preserved.
- If it matches more than 1 row in `y`, it's duplicated once for each match.

In principle, this means that there's no guaranteed correspondence between the rows in the output and the rows in the `x`:

- There might be fewer rows if some rows in `x` don't match any rows in `y`.
- There might be more rows if some rows in `x` match multiple rows in `y`.
- There might be the same number of rows if every row in `x` matches one row in `y`.
- There might be the same number of rows if some rows don't match any rows, and exactly the same number of rows match two rows in `y` !!

Row expansion is a fundamental property of joins, but it's dangerous because it might happen without you realizing it. To avoid this problem, `dplyr` will warn whenever there are multiple matches:

```
df1 <- tibble(key = c(1, 2, 3), val_x = c("x1", "x2", "x3"))
df2 <- tibble(key = c(1, 2, 2), val_y = c("y1", "y2", "y3"))

df1 |>
  inner_join(df2, join_by(key))
#> Warning in inner_join(df1, df2, join_by(key)): Each row of `x` has
#> 2 or more matching rows in `y`.
#> If multiple matches are expected, set `multiple = "warn".
#> # A tibble: 3 × 3
#>   key     val_x   val_y
#>   <dbl> <chr> <chr>
#> 1     1     x1     y1
#> 2     2     x2     y1
#> 3     2     x3     y2
```

```
#> 2      2 x2      y2  
#> 3      2 x2      y3
```

This is one reason we like `left_join()` — if it runs without warning, you know that each row of the output matches the row in the same position in `x`.

You can gain further control over row matching with two arguments:

- `unmatched` controls what happens when a row in `x` fails to match any rows in `y`. It defaults to "drop" which will silently drop any unmatched rows.
- `multiple` controls what happens when a row in `x` matches more than one row in `y`. For equi-joins, it defaults to "warn" which emits a warning message if any rows have multiple matches.

There are two common cases in which you might want to override these defaults: enforcing a one-to-one mapping or deliberately allowing the rows to increase.

21.4.2 One-to-one mapping

Both `unmatched` and `multiple` can take value "error" which means that the join will fail unless each row in `x` matches exactly one row in `y`:

```
df1 <- tibble(x = 1)  
df2 <- tibble(x = c(1, 1))  
df3 <- tibble(x = 3)  
  
df1 |>  
  inner_join(df2, join_by(x), unmatched = "error", multi  
#> Error in `inner_join()`:  
#> ! Each row in `x` must match at most 1 row in `y`.  
#> i Row 1 of `x` matches multiple rows.
```

```
df1 |>
  inner_join(df3, join_by(x), unmatched = "error", multi
#> Error in `inner_join()`:
#> ! Each row of `x` must have a match in `y`.
#> i Row 1 of `x` does not have a match.
```

Note that `unmatched = "error"` is not useful with `left_join()` because, as described above, every row in `x` has a fallback match to a virtual row in `y`.

21.4.3 Allow multiple rows

Sometimes it's useful to deliberately expand the number of rows in the output. This can come about naturally if you “flip” the direction of the question you're asking. For example, as we've seen above, it's natural to supplement the `flights` data with information about the plane that flew each flight:

```
flights2 |>
  left_join(planes, by = "tailnum")
```

But it's also reasonable to ask what flights did each plane fly:

```
plane_flights <- planes |>
  select(tailnum, type, engines, seats) |>
  left_join(flights2, by = "tailnum")
#> Warning in left_join(select(planes, tailnum, type, en
#> i Row 1 of `x` matches multiple rows.
#> i If multiple matches are expected, set `multiple = "
#>   warning.
```

Since this duplicates rows in `x` (the planes), we need to explicitly say that we're ok with the multiple matches by setting `multiple = "all"`:

```
plane_flights <- planes |>
  select(tailnum, type, engines, seats) |>
  left_join(flights2, by = "tailnum", multiple = "all")

plane_flights
#> # A tibble: 284,170 × 9
#>   tailnum type    engines seats year time_hour
#>   <chr>   <chr>     <int> <int> <int> <dttm>
#> 1 N10156 Fixed...     2     55  2013 2013-01-10 06:00
#> 2 N10156 Fixed...     2     55  2013 2013-01-10 10:00
#> 3 N10156 Fixed...     2     55  2013 2013-01-10 15:00
#> 4 N10156 Fixed...     2     55  2013 2013-01-11 06:00
#> 5 N10156 Fixed...     2     55  2013 2013-01-11 11:00
#> 6 N10156 Fixed...     2     55  2013 2013-01-11 18:00
#> # ... with 284,164 more rows
```

21.4.4 Filtering joins

The number of matches also determines the behavior of the filtering joins. The semi-join keeps rows in `x` that have one or more matches in `y`, as in [Figure 21.10](#). The anti-join keeps rows in `x` that match zero rows in `y`, as in [Figure 21.11](#). In both cases, only the existence of a match is important; it doesn't matter how many times it matches. This means that filtering joins never duplicate rows like mutating joins do.

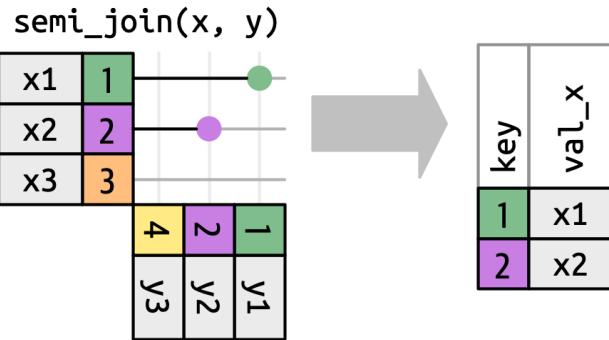

Figure 21.10: In a semi-join it only matters that there is a match; otherwise values in `y` don't affect the output.

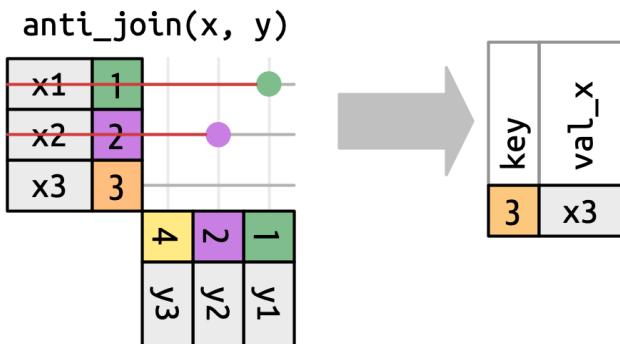

Figure 21.11: An anti-join is the inverse of a semi-join, dropping rows from `x` that have a match in `y`.

21.5 Non-equi joins

So far you've only seen equi-joins, joins where the rows match if the `x` key equals the `y` key. Now we're going to relax that restriction and discuss other ways of determining if a pair of rows match.

But before we can do that, we need to revisit a simplification we made above. In equi-joins the `x` keys and `y` are always equal, so we only need to show one in the output. We can request that `dplyr` keep both keys with `keep = TRUE`, leading to the code below and the re-drawn `inner_join()` in [Figure 21.12](#).

```
x |> left_join(y, by = "key", keep = TRUE)
#> # A tibble: 3 × 4
#>   key.x val_x key.y val_y
#>   <dbl> <chr> <dbl> <chr>
#> 1     1 x1      1 y1
#> 2     2 x2      2 y2
#> 3     3 x3     NA <NA>
```

`join_by(key == key)`

| | | | |
|----|---|----|----|
| x1 | 1 | | |
| x2 | 2 | | |
| x3 | 3 | | |
| | | 4 | -1 |
| | | y3 | y2 |
| | | | y1 |

| key.x | val_x | key.y | val_y |
|-------|-------|-------|-------|
| 1 | x1 | 1 | y1 |
| 2 | x2 | 2 | y2 |

Figure 21.12: A left join showing both `x` and `y` keys in the output.

When we move away from equi-joins we'll always show the keys, because the key values will often be different. For example, instead of matching only when the `x$key` and `y$key` are equal, we could match whenever the `x$key` is greater than or equal to the `y$key`, leading to [Figure 21.13](#). `dplyr`'s join functions understand this distinction equi and non-equi joins so will always show both keys when you perform a non-equi join.

`join_by(key >= key)`

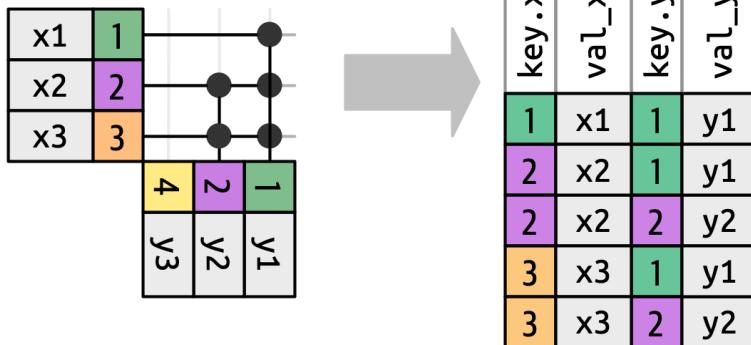

Figure 21.13: A non-equi join where the `x` key must greater than or equal to than the `y` key. Many rows generate multiple matches.

Non-equi-join isn't a particularly useful term because it only tells you what the join is not, not what it is. `dplyr` helps by identifying four particularly useful types of non-equi-join:

- **Cross joins** match every pair of rows.
- **Inequality joins** use `<`, `<=`, `>`, and `>=` instead of `==`.
- **Rolling joins** are similar to inequality joins but only find the closest match.
- **Overlap joins** are a special type of inequality join designed to work with ranges.

Each of these is described in more detail in the following sections.

21.5.1 Cross joins

A cross join matches everything, as in [Figure 21.14](#), generating the Cartesian product of rows. This means the output will have `nrow(x) * nrow(y)` rows.

join_by()

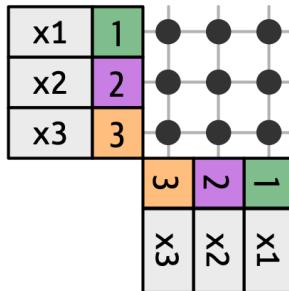

Figure 21.14: A cross join matches each row in `x` with every row in `y`.

Cross joins are useful when generating permutations. For example, the code below generates every possible pair of names. Since we're joining `df` to itself, this is sometimes called a **self-join**. Cross joins use a different join function because there's no distinction between inner/left/right/full when you're matching every row.

```
df <- tibble(name = c("John", "Simon", "Tracy", "Max"))
df |> cross_join(df)
#> # A tibble: 16 × 2
#>   name.x name.y
#>   <chr>  <chr>
#> 1 John    John
#> 2 John    Simon
#> 3 John    Tracy
#> 4 John    Max
#> 5 Simon   John
#> 6 Simon   Simon
#> # ... with 10 more rows
```

21.5.2 Inequality joins

Inequality joins use `<`, `<=`, `>=`, or `>` to restrict the set of possible matches, as in [Figure 21.13](#) and [Figure 21.15](#).

`join_by(key < key)`

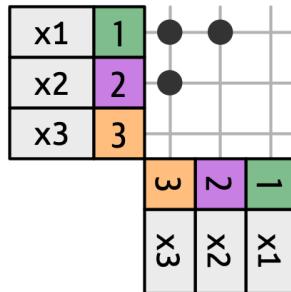

Figure 21.15: An inequality join where `x` is joined to `y` on rows where the key of `x` is less than the key of `y`. This makes a triangular shape in the top-left corner.

Inequality joins are extremely general, so general that it's hard to come up with meaningful specific use cases. One small useful technique is to use them to restrict the cross join so that instead of generating all permutations, we generate all combinations:

```
df <- tibble(id = 1:4, name = c("John", "Simon", "Tracy"))

df |> left_join(df, join_by(id < id))
#> # A tibble: 7 × 4
#>   id.x name.x   id.y name.y
#>   <int> <chr>    <int> <chr>
#> 1     1 John      2 Simon
#> 2     1 John      3 Tracy
#> 3     1 John      4 Max
#> 4     2 Simon     3 Tracy
#> 5     2 Simon     4 Max
#> 6     3 Tracy     4 Max
#> # ... with 1 more row
```

21.5.3 Rolling joins

Rolling joins are a special type of inequality join where instead of getting every row that satisfies the inequality, you get just the closest row, as in [Figure 21.16](#). You can turn any inequality join into a rolling join by adding `closest()`. For example `join_by(closest(x <= y))` matches the smallest `y` that's greater than or equal to `x`, and `join_by(closest(x > y))` matches the biggest `y` that's less than `x`.

`join_by(closest(key <= key))`

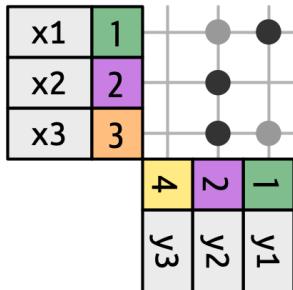

Figure 21.16: A following join is similar to a greater-than-or-equal inequality join but only matches the first value.

Rolling joins are particularly useful when you have two tables of dates that don't perfectly line up and you want to find (e.g.) the closest date in table 1 that comes before (or after) some date in table 2.

For example, imagine that you're in charge of the party planning commission for your office. Your company is rather cheap so instead of having individual parties, you only have a party once each quarter. The rules for determining when a party will be held are a little complex: parties are always on a Monday, you skip the first week of January since a lot of people are on holiday, and the first Monday of Q3 2022 is July 4,

so that has to be pushed back a week. That leads to the following party days:

```
parties <- tibble(  
  q = 1:4,  
  party = lubridate::ymd(c("2022-01-10", "2022-04-04", "  
)
```

Now imagine that you have a table of employee birthdays:

```
employees <- tibble(  
  name = wakefield::name(100),  
  birthday = lubridate::ymd("2022-01-01") + (sample(365,  
)  
employees  
#> # A tibble: 100 × 2  
#>   name      birthday  
#>   <variable> <date>  
#> 1 Lindzy    2022-08-11  
#> 2 Santania   2022-03-01  
#> 3 Gardell    2022-03-04  
#> 4 Cyrille    2022-11-15  
#> 5 Kynli      2022-07-09  
#> 6 Sever      2022-02-03  
#> # ... with 94 more rows
```

And for each employee we want to find the first party date that comes after (or on) their birthday. We can express that with a rolling join:

```
employees |>  
  left_join(parties, join_by(closest(birthday >= party)))  
#> # A tibble: 100 × 4
```

```
#>   name      birthday      q party
#>   <variable> <date>      <int> <date>
#> 1 Lindzy    2022-08-11    3 2022-07-11
#> 2 Santania  2022-03-01    1 2022-01-10
#> 3 Gardell   2022-03-04    1 2022-01-10
#> 4 Cyrille   2022-11-15    4 2022-10-03
#> 5 Kynli     2022-07-09    2 2022-04-04
#> 6 Sever     2022-02-03    1 2022-01-10
#> # ... with 94 more rows
```

There is, however, one problem with this approach: the folks with birthdays before January 10 don't get a party:

```
employees |>
  anti_join(parties, join_by(closest(birthday >= party)))
#> # A tibble: 4 × 2
#>   name      birthday
#>   <variable> <date>
#> 1 Janeida  2022-01-04
#> 2 Aires     2022-01-07
#> 3 Mikalya   2022-01-06
#> 4 Carlynn   2022-01-08
```

To resolve that issue we'll need to tackle the problem a different way, with overlap joins.

21.5.4 Overlap joins

Overlap joins provide three helpers that use inequality joins to make it easier to work with intervals:

- `between(x, y_lower, y_upper)` is short for `x >= y_lower, x <= y_upper`.

- `within(x_lower, x_upper, y_lower, y_upper)` is short for `x_lower >= y_lower, x_upper <= y_upper`.
- `overlaps(x_lower, x_upper, y_lower, y_upper)` is short for `x_lower <= y_upper, x_upper >= y_lower`.

Let's continue the birthday example to see how you might use them. There's one problem with the strategy we used above: there's no party preceding the birthdays Jan 1-9. So it might be better to be explicit about the date ranges that each party spans, and make a special case for those early birthdays:

```
parties <- tibble(  
  q = 1:4,  
  party = lubridate::ymd(c("2022-01-10", "2022-04-04", "  
  start = lubridate::ymd(c("2022-01-01", "2022-04-04", "  
  end = lubridate::ymd(c("2022-04-03", "2022-07-11", "20  
)  
parties  
#> # A tibble: 4 × 4  
#>   q     party      start      end  
#>   <int> <date>     <date>     <date>  
#> 1     1 2022-01-10 2022-01-01 2022-04-03  
#> 2     2 2022-04-04 2022-04-04 2022-07-11  
#> 3     3 2022-07-11 2022-07-11 2022-10-02  
#> 4     4 2022-10-03 2022-10-03 2022-12-31
```

Hadley is hopelessly bad at data entry so he also wanted to check that the party periods don't overlap. One way to do this is by using a self-join to check to if any start-end interval overlap with another:

```
parties |>  
  inner_join(parties, join_by(overlaps(start, end, start  
  select(start.x, end.x, start.y, end.y)
```

```
#> # A tibble: 1 × 4
#>   start.x     end.x      start.y     end.y
#>   <date>     <date>     <date>     <date>
#> 1 2022-04-04 2022-07-11 2022-07-11 2022-10-02
```

Oops, there is an overlap, so let's fix that problem and continue:

```
parties <- tibble(
  q = 1:4,
  party = lubridate::ymd(c("2022-01-10", "2022-04-04", "2022-07-11", "2022-10-02"),
  start = lubridate::ymd(c("2022-01-01", "2022-04-04", "2022-07-10", "2022-10-01"),
  end = lubridate::ymd(c("2022-04-03", "2022-07-10", "2022-10-01", "2023-01-01"))
)
```

Now we can match each employee to their party. This is a good place to use `unmatched = "error"` because we want to quickly find out if any employees didn't get assigned a party.

```
employees |>
  inner_join(parties, join_by(between(birthday, start, end),
  #> # A tibble: 100 × 6
  #>   name      birthday      q party      start      end
  #>   <variable> <date>    <int> <date>     <date>     <date>
  #> 1 Lindzy    2022-08-11    3 2022-07-11 2022-07-11 2022-08-11
  #> 2 Santania   2022-03-01    1 2022-01-10 2022-01-01 2022-03-01
  #> 3 Gardell    2022-03-04    1 2022-01-10 2022-01-01 2022-03-04
  #> 4 Cyrille    2022-11-15    4 2022-10-03 2022-10-03 2022-11-15
  #> 5 Kynli      2022-07-09    2 2022-04-04 2022-04-04 2022-07-09
  #> 6 Sever      2022-02-03    1 2022-01-10 2022-01-01 2022-02-03
  #> # ... with 94 more rows
```

21.5.5 Exercises

1. Can you explain what's happening with the keys in this equi-join?
Why are they different?

```
x |> full_join(y, by = "key")
#> # A tibble: 4 × 3
#>   key val_x val_y
#>   <dbl> <chr> <chr>
#> 1     1 x1    y1
#> 2     2 x2    y2
#> 3     3 x3    <NA>
#> 4     4 <NA>  y3

x |> full_join(y, by = "key", keep = TRUE)
#> # A tibble: 4 × 4
#>   key.x val_x key.y val_y
#>   <dbl> <chr> <dbl> <chr>
#> 1     1 x1      1 y1
#> 2     2 x2      2 y2
#> 3     3 x3      NA <NA>
#> 4     NA <NA>     4 y3
```

2. When finding if any party period overlapped with another party period we used `q < q` in the `join_by()`? Why? What happens if you remove this inequality?

21.6 Summary

In this chapter, you've learned how to use mutating and filtering joins to combine data from a pair of data frames. Along the way you learned how to identify keys, and the difference between primary and foreign keys. You also understand how joins work and how to figure out how many

rows the output will have. Finally, you've gained a glimpse into the power of non-equi-joins and seen a few interesting use cases.

This chapter concludes the “Transform” part of the book where the focus was on the tools you could use with individual columns and tibbles. You learned about dplyr and base functions for working with logical vectors, numbers, and complete tables, stringr functions for working strings, lubridate functions for working with date-times, andforcats functions for working with factors.

In the next part of the book, you’ll learn more about getting various types of data into R in a tidy form.

1. Remember that in RStudio you can also use `View()` to avoid this problem. 
2. That’s not 100% true, but you’ll get a warning whenever it isn’t. 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

In this part of the book, you'll learn how to import a wider range of data into R, as well as how to get it into a form useful form for analysis.

Sometimes this is just a matter of calling a function from the appropriate data import package. But in more complex cases it might require both tidying and transformation in order to get to the tidy rectangle that you'd prefer to work with.

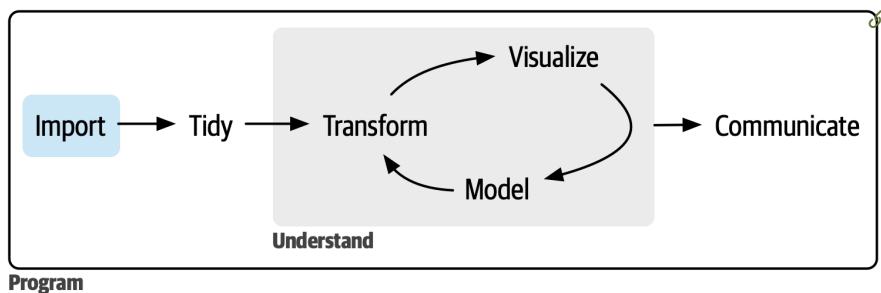

Figure 1: Data import is the beginning of the data science process; without data you can't do data science!

In this part of the book you'll learn how to access data stored in the following ways:

- In [Chapter 22](#), you'll learn how to import data from Excel spreadsheets and Google Sheets.
- In [Chapter 23](#), you'll learn about getting data out of a database and into R (and you'll also learn a little about how to get data out of R and into a database).
- In [Chapter 24](#), you'll learn about Arrow, a powerful tool for working with out-of-memory data, particularly when it's stored in the

parquet format.

- In [Chapter 25](#), you'll learn how to work with hierarchical data, including the deeply nested lists produced by data stored in the JSON format.
- In [Chapter 26](#), you'll learn web “scraping”, the art and science of extracting data from web pages.

There are two important tidyverse packages that we don't discuss here: haven and xml2. If you're working with data from SPSS, Stata, and SAS files, check out the **haven** package, <https://haven.tidyverse.org>. If you're working with XML data, check out the **xml2** package, <https://xml2.r-lib.org>. Otherwise, you'll need to do some research to figure which package you'll need to use; Google is your friend here 😊.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

22.1 Introduction

So far, you have learned about importing data from plain text files, e.g., `.csv` and `.tsv` files. Sometimes you need to analyze data that lives in a spreadsheet. This chapter will introduce you to tools for working with data in Excel spreadsheets and Google Sheets. This will build on much of what you've learned in [Chapter 8](#), but we will also discuss additional considerations and complexities when working with data from spreadsheets.

If you or your collaborators are using spreadsheets for organizing data, we strongly recommend reading the paper “Data Organization in Spreadsheets” by Karl Broman and Kara Woo:
<https://doi.org/10.1080/00031305.2017.1375989>. The best practices presented in this paper will save you much headache when you import data from a spreadsheet into R to analyze and visualize.

22.2 Excel

22.2.1 Prerequisites

In this section, you'll learn how to load data from Excel spreadsheets in R with the `readxl` package. This package is non-core tidyverse, so you need to load it explicitly, but it is installed automatically when you install the tidyverse package.

```
library(readxl)  
library(tidyverse)
```

`openxlsx`, `xlsx`, and `XLConnect` can also be used for reading data from and writing data to Excel spreadsheets. We will discuss `openxlsx` in [Section 22.2.8](#). The latter two packages require Java installed on your machine and the `rJava` package. Due to potential challenges with installation, we recommend using alternative packages we're introducing in this chapter.

22.2.2 Getting started

Most of `readxl`'s functions allow you to load Excel spreadsheets into R:

- `read_xls()` reads Excel files with `xls` format.
- `read_xlsx()` read Excel files with `xlsx` format.
- `read_excel()` can read files with both `xls` and `xlsx` format. It guesses the file type based on the input.

These functions all have similar syntax just like other functions we have previously introduced for reading other types of files, e.g. `read_csv()`, `read_table()`, etc. For the rest of the chapter we will focus on using `read_excel()`.

22.2.3 Reading spreadsheets

[Figure 22.1](#) shows what the spreadsheet we're going to read into R looks like in Excel.

The screenshot shows a Microsoft Excel spreadsheet titled "students". The data is organized into five columns: "Student ID", "Full Name", "favourite.food", "mealPlan", and "AGE". The rows contain the following data:

| | A | B | C | D | E |
|---|------------|------------------|--------------------|---------------------|------|
| 1 | Student ID | Full Name | favourite.food | mealPlan | AGE |
| 2 | 1 | Sunil Huffmann | Strawberry yoghurt | Lunch only | 4 |
| 3 | 2 | Barclay Lynn | French fries | Lunch only | 5 |
| 4 | 3 | Jayendra Lyne | N/A | Breakfast and lunch | 7 |
| 5 | 4 | Leon Rossini | Anchovies | Lunch only | |
| 6 | 5 | Chidiegwu Dunkel | Pizza | Breakfast and lunch | five |
| 7 | 6 | Güvenç Attila | Ice cream | Lunch only | 6 |

Figure 22.1: Spreadsheet called `students.xlsx` in Excel.

The first argument to `read_excel()` is the path to the file to read.

```
students <- read_excel("data/students.xlsx")
```

`read_excel()` will read the file in as a tibble.

```
students
#> # A tibble: 6 × 5
#>   `Student ID` `Full Name`    favourite.food     mealPlan   AGE
#>       <dbl> <chr>           <chr>            <chr>
#> 1        1 Sunil Huffmann  Strawberry yoghurt Lunch only  4
#> 2        2 Barclay Lynn   French fries      Lunch only  5
#> 3        3 Jayendra Lyne  N/A              Breakfast and lunch 7
#> 4        4 Leon Rossini   Anchovies      Lunch only
#> 5        5 Chidiegwu Dunkel Pizza          Breakfast and lunch
#> 6        6 Güvenç Attila  Ice cream      Lunch only  6
```

We have six students in the data and five variables on each student. However there are a few things we might want to address in this dataset:

1. The column names are all over the place. You can provide column names that follow a consistent format; we recommend `snake_case` using the `col_names` argument.

```
read_excel(  
  "data/students.xlsx",  
  col_names = c("student_id", "full_name", "favourit  
)  
#> # A tibble: 7 × 5  
#>   student_id full_name      favourite_food  
#>   <chr>       <chr>          <chr>  
#> 1 Student ID Full Name  favourite.food  
#> 2 1           Sunil Huffmann Strawberry yoghurt  
#> 3 2           Barclay Lynn    French fries  
#> 4 3           Jayendra Lyne  N/A  
#> 5 4           Leon Rossini   Anchovies  
#> 6 5           Chidiegwu Dunkel Pizza  
#> 7 6           Güvenç Attila  Ice cream
```

Unfortunately, this didn't quite do the trick. We now have the variable names we want, but what was previously the header row now shows up as the first observation in the data. You can explicitly skip that row using the `skip` argument.

```
read_excel(  
  "data/students.xlsx",  
  col_names = c("student_id", "full_name", "favourit  
  skip = 1  
)  
#> # A tibble: 6 × 5
```

```
#>   student_id full_name      favourite_food
#>   <dbl> <chr>            <chr>
#> 1     1 Sunil Huffmann    Strawberry yoghurt
#> 2     2 Barclay Lynn       French fries
#> 3     3 Jayendra Lyne     N/A
#> 4     4 Leon Rossini      Anchovies
#> 5     5 Chidiegwu Dunkel Pizza
#> 6     6 Güvenç Attila     Ice cream
```

2. In the `favourite_food` column, one of the observations is `N/A`, which stands for “not available” but it’s currently not recognized as an `NA` (note the contrast between this `N/A` and the age of the fourth student in the list). You can specify which character strings should be recognized as `NA`s with the `na` argument. By default, only `""` (empty string, or, in the case of reading from a spreadsheet, an empty cell or a cell with the formula `=NA()`) is recognized as an `NA`.

```
read_excel(
  "data/students.xlsx",
  col_names = c("student_id", "full_name", "favourite_food"),
  skip = 1,
  na = c("", "N/A"))
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food
#>   <dbl> <chr>            <chr>
#> 1     1 Sunil Huffmann    Strawberry yoghurt
#> 2     2 Barclay Lynn       French fries
#> 3     3 Jayendra Lyne     <NA>
#> 4     4 Leon Rossini      Anchovies
#> 5     5 Chidiegwu Dunkel Pizza
#> 6     6 Güvenç Attila     Ice cream
```

3. One other remaining issue is that `age` is read in as a character variable, but it really should be numeric. Just like with `read_csv()` and friends for reading data from flat files, you can supply a `col_types` argument to `read_excel()` and specify the column types for the variables you read in. The syntax is a bit different, though. Your options are "skip", "guess", "logical", "numeric", "date", "text" or "list".

```
read_excel(  
  "data/students.xlsx",  
  col_names = c("student_id", "full_name", "favourite_food"),  
  skip = 1,  
  na = c("", "N/A"),  
  col_types = c("numeric", "text", "text", "text", "  
)  
#> Warning: Expecting numeric in E6 / R6C5: got 'five'  
#> # A tibble: 6 × 5  
#>   student_id full_name      favourite_food  
#>       <dbl> <chr>          <chr>  
#> 1           1 Sunil Huffmann  Strawberry yoghurt  
#> 2           2 Barclay Lynn   French fries  
#> 3           3 Jayendra Lyne  <NA>  
#> 4           4 Leon Rossini   Anchovies  
#> 5           5 Chidiegwu Dunkel Pizza  
#> 6           6 Güvenç Attila  Ice cream
```

However, this didn't quite produce the desired result either. By specifying that `age` should be numeric, we have turned the one cell with the non-numeric entry (which had the value `five`) into an `NA`. In this case, we should read `age` in as "text" and then make the change once the data is loaded in R.

```

students <- read_excel(
  "data/students.xlsx",
  col_names = c("student_id", "full_name", "favourite_food"),
  skip = 1,
  na = c("", "N/A"),
  col_types = c("numeric", "text", "text", "text", "text")
)

students <- students |>
  mutate(
    age = if_else(age == "five", "5", age),
    age = parse_number(age)
  )

students
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food
#>   <dbl> <chr>           <chr>
#> 1 1 Sunil Huffmann  Strawberry yoghurt
#> 2 2 Barclay Lynn   French fries
#> 3 3 Jayendra Lyne  <NA>
#> 4 4 Leon Rossini   Anchovies
#> 5 5 Chidiegwu Dunkel Pizza
#> 6 6 Güvenç Attila   Ice cream

```

It took us multiple steps and trial-and-error to load the data in exactly the format we want, and this is not unexpected. Data science is an iterative process, and the process of iteration can be even more tedious when reading data in from spreadsheets compared to other plain text, rectangular data files because humans tend to input data into spreadsheets and use them not just for data storage but also for sharing and communication.

There is no way to know exactly what the data will look like until you load it and take a look at it. Well, there is one way, actually. You can open the file in Excel and take a peek. If you’re going to do so, we recommend making a copy of the Excel file to open and browse interactively while leaving the original data file untouched and reading into R from the untouched file. This will ensure you don’t accidentally overwrite anything in the spreadsheet while inspecting it. You should also not be afraid of doing what we did here: load the data, take a peek, make adjustments to your code, load it again, and repeat until you’re happy with the result.

22.2.4 Reading worksheets

An important feature that distinguishes spreadsheets from flat files is the notion of multiple sheets, called worksheets. [Figure 22.2](#) shows an Excel spreadsheet with multiple worksheets. The data come from the **palmerpenguins** package. Each worksheet contains information on penguins from a different island where data were collected.

Figure 22.2: Spreadsheet called `penguins.xlsx` in Excel containing three worksheets.

You can read a single worksheet from a spreadsheet with the `sheet` argument in `read_excel()`.

```
read_excel("data/penguins.xlsx", sheet = "Torgersen Island")
#> # A tibble: 52 × 8
#>   species     island   bill_length_mm   bill_depth_mm   flipper_length_mm   body_mass_g   sex   year
#>   <chr>      <chr>        <dbl>            <dbl>              <dbl>           <dbl>    <chr>  <dbl>
#> 1 Adelie     Torgersen     39.1            18.7              181            3750   male   2007
#> 2 Adelie     Torgersen     39.5            17.4              186            3800   female  2007
#> 3 Adelie     Torgersen     40.3            18                195            3250   female  2007
#> 4 Adelie     Torgersen     NA               NA                NA             NA    female  2007
#> 5 Adelie     Torgersen     36.7            19.3              193            3450   female  2007
#> 6 Adelie     Torgersen     39.3            20.6              190            3650   male   2007
#> 7 Adelie     Torgersen     38.9            17.8              181            3625   female  2007
#> 8 Adelie     Torgersen     39.2            19.6              195            4675   male   2007
#> 9 Adelie     Torgersen     34.1            18.1              193            3475   NA    2007
#> 10 Adelie    Torgersen     42               20.2              190            4250   NA    2007
#> 11 Adelie    Torgersen     37.8            17.1              186            3300   NA    2007
#> 12 Adelie    Torgersen     37.8            17.3              180            3700   NA    2007
#> 13 Adelie    Torgersen     41.1            17.6              182            3200   female  2007
#> 14 Adelie    Torgersen     38.6            21.2              191            3800   male   2007
#> 15 Adelie    Torgersen     34.6            21.1              198            4400   male   2007
#> 16 Adelie    Torgersen     36.6            17.8              185            3700   female  2007
#> 17 Adelie    Torgersen     38.7            19                195            3450   female  2007
#> 18 Adelie    Torgersen     37.8            17.3              180            4500   NA    2007
#> # ... with 46 more rows, and abbreviated variable names
#> #   `flipper_length_mm` <- flipper_length_mm, `body_mass_g` <- body_mass_g
```

Some variables that appear to contain numerical data are read in as characters due to the character string "NA" not being recognized as a true NA.

```
penguins_torgersen <- read_excel("data/penguins.xlsx", s  
penguins_torgersen  
#> # A tibble: 52 × 8  
#>   species island    bill_length_mm bill_depth_mm flipper_length_mm body_mass_g  
#>   <chr>   <chr>          <dbl>           <dbl>             <dbl>            <dbl>  
#> 1 Adelie  Torgersen      39.1            18.7              188.             375.  
#> 2 Adelie  Torgersen      39.5            17.4              181.             391.  
#> 3 Adelie  Torgersen      40.3            18.0              193.             450.  
#> 4 Adelie  Torgersen      NA               NA                NA               NA  
#> 5 Adelie  Torgersen      36.7            19.3              164.             344.  
#> 6 Adelie  Torgersen      39.3            20.6              193.             437.  
#> # ... with 46 more rows, and abbreviated variable names  
#> #   `body_mass_g`
```

Alternatively, you can use `excel_sheets()` to get information on all worksheets in an Excel spreadsheet, and then read the one(s) you're interested in.

```
excel_sheets("data/penguins.xlsx")  
#> [1] "Torgersen Island" "Biscoe Island"     "Dream Islan
```

Once you know the names of the worksheets, you can read them in individually with `read_excel()`.

```
penguins_biscoe <- read_excel("data/penguins.xlsx", shee
```

```
penguins_dream <- read_excel("data/penguins.xlsx", sheet = "Dream")
```

In this case the full penguins dataset is spread across three worksheets in the spreadsheet. Each worksheet has the same number of columns but different numbers of rows.

```
dim(penguins_torgersen)
#> [1] 52   8
dim(penguins_biscoe)
#> [1] 168  8
dim(penguins_dream)
#> [1] 124  8
```

We can put them together with `bind_rows()`.

```
penguins <- bind_rows(penguins_torgersen, penguins_biscoe,
penguins
#> # A tibble: 344 × 8
#>   species     island   bill_length_mm bill_depth_mm flipper_length_mm
#>   <chr>      <chr>           <dbl>          <dbl>            <dbl>
#> 1 Adelie    Torgersen       39.1          18.7             18.7
#> 2 Adelie    Torgersen       39.5          17.4             17.4
#> 3 Adelie    Torgersen       40.3           18               18
#> 4 Adelie    Torgersen        NA              NA               NA
#> 5 Adelie    Torgersen       36.7          19.3             19.3
#> 6 Adelie    Torgersen       39.3          20.6             20.6
#> # ... with 338 more rows, and abbreviated variable name
#> #   `body_mass_g`
```

In [Chapter 28](#) we'll talk about ways of doing this sort of task without repetitive code.

22.2.5 Reading part of a sheet

Since many use Excel spreadsheets for presentation as well as for data storage, it's quite common to find cell entries in a spreadsheet that are not part of the data you want to read into R. [Figure 22.3](#) shows such a spreadsheet: in the middle of the sheet is what looks like a data frame but there is extraneous text in cells above and below the data.

| | A | B | C | D | E | F | G | H | I |
|----|-----------------|--------------------------|-----|----------|---------------|---------------|---|---|---|
| 1 | For the sake | | | | | | | | |
| 2 | of consistency | | | | in the | | | | |
| 3 | which is really | | | | a | | | | |
| 4 | I will | keep making notes | | | | | | | |
| 5 | Name | Profession | Age | Has kids | Date of birth | Date of death | | | |
| 6 | Vera Rubin | scientist | 88 | TRUE | 23/07/1928 | 25/12/2016 | | | |
| 7 | Mohamed Ali | athlete | 74 | TRUE | 17/01/1942 | 03/06/2016 | | | |
| 8 | Morley Safer | journalist | 84 | TRUE | 08/11/1931 | 19/05/2016 | | | |
| 9 | Fidel Castro | politician | 90 | TRUE | 13/08/1926 | 25/11/2016 | | | |
| 10 | Antonin Scalia | lawyer | 79 | TRUE | 11/03/1936 | 13/02/2016 | | | |
| 11 | Jo Cox | politician | 41 | TRUE | 22/06/1974 | 16/06/2016 | | | |
| 12 | Janet Reno | lawyer | 78 | FALSE | 21/07/1938 | 07/11/2016 | | | |
| 13 | Gwen Ifill | journalist | 61 | FALSE | 29/09/1955 | 14/11/2016 | | | |
| 14 | John Glenn | astronaut | 95 | TRUE | 28/07/1921 | 08/12/2016 | | | |
| 15 | Pat Summit | coach | 64 | TRUE | 14/06/1952 | 28/06/2016 | | | |
| 16 | This | | | | | | | | |
| 17 | | has been really fun, but | | | | | | | |
| 18 | we're signing | | | | | | | | |
| 19 | | | off | | | now! | | | |

Figure 22.3: Spreadsheet called deaths.xlsx in Excel.

This spreadsheet is one of the example spreadsheets provided in the `readxl` package. You can use the `readxl_example()` function to locate the spreadsheet on your system in the directory where the package is installed. This function returns the path to the spreadsheet, which you can use in `read_excel()` as usual.

```
deaths_path <- readxl_example("deaths.xlsx")
deaths <- read_excel(deaths_path)
#> New names:
```

```
#> • `` -> `...2`  
#> • `` -> `...3`  
#> • `` -> `...4`  
#> • `` -> `...5`  
#> • `` -> `...6`  
deaths  
#> # A tibble: 18 × 6  
#>   `Lots of people` ...2 ...3 ...4  
#>   <chr>      <chr> <chr> <chr>  
#> 1 simply cannot resist writing <NA> <NA> <NA>  
#> 2 at                      the    top   <NA>  
#> 3 or                      merging <NA> <NA>  
#> 4 Name                     Profession Age  Has k  
#> 5 David Bowie              musician  69   TRUE  
#> 6 Carrie Fisher            actor    60   TRUE  
#> # ... with 12 more rows
```

The top three rows and the bottom four rows are not part of the data frame.

We could skip the top three rows with `skip`. Note that we set `skip = 4` since the fourth row contains column names, not the data.

```
read_excel(deaths_path, skip = 4)  
#> # A tibble: 14 × 6  
#>   Name      Profession Age  `Has kids` `Date of  
#>   <chr>      <chr>     <chr> <chr>    <dttm>  
#> 1 David Bowie  musician  69   TRUE     1947-01-0  
#> 2 Carrie Fisher actor    60   TRUE     1956-10-2  
#> 3 Chuck Berry  musician  90   TRUE     1926-10-1  
#> 4 Bill Paxton  actor    61   TRUE     1955-05-1  
#> 5 Prince       musician  57   TRUE     1958-06-6
```

```
#> 6 Alan Rickman actor      69 FALSE 1946-02-2
#> # ... with 8 more rows, and abbreviated variable name ^
```

We could also set `n_max` to omit the extraneous rows at the bottom.

```
read_excel(deaths_path, skip = 4, n_max = 10)
#> # A tibble: 10 × 6
#>   Name       Prof...¹ Age Has k...² `Date of birth`
#>   <chr>     <chr>  <dbl> <lgl>  <dttm>
#> 1 David Bowie musician... 69 TRUE  1947-01-08 00:00:00
#> 2 Carrie Fisher actor    60 TRUE  1956-10-21 00:00:00
#> 3 Chuck Berry musician... 90 TRUE  1926-10-18 00:00:00
#> 4 Bill Paxton actor     61 TRUE  1955-05-17 00:00:00
#> 5 Prince      musician... 57 TRUE  1958-06-07 00:00:00
#> 6 Alan Rickman actor      69 FALSE 1946-02-21 00:00:00
#> # ... with 4 more rows, and abbreviated variable names
#> #   ^`Has kids`
```

Another approach is using cell ranges. In Excel, the top left cell is `A1`. As you move across columns to the right, the cell label moves down the alphabet, i.e. `B1`, `C1`, etc. And as you move down a column, the number in the cell label increases, i.e. `A2`, `A3`, etc.

The data we want to read in starts in cell `A5` and ends in cell `F15`. In spreadsheet notation, this is `A5:F15`.

- Supply this information to the `range` argument:

```
read_excel(deaths_path, range = "A5:F15")
```

- Specify rows:

```
read_excel(deaths_path, range = cell_rows(c(5, 15)))
```

22.2.6 Data types

In CSV files, all values are strings. This is not particularly true to the data, but it is simple: everything is a string.

The underlying data in Excel spreadsheets is more complex. A cell can be one of five things:

- A boolean, like TRUE, FALSE, or NA
- A number, like “10” or “10.5”
- A datetime, which can also include time like “11/1/21” or “11/1/21 3:00 PM”
- A text string, like “ten”

When working with spreadsheet data, it’s important to keep in mind that how the underlying data is stored can be very different than what you see in the cell. For example, Excel has no notion of an integer. All numbers are stored as floating points, but you can choose to display the data with a customizable number of decimal points. Similarly, dates are actually stored as numbers, specifically the number of seconds since January 1, 1970. You can customize how you display the date by applying formatting in Excel. Confusingly, it’s also possible to have something that looks like a number but is actually a string (e.g. type ‘10 into a cell in Excel).

These differences between how the underlying data are stored vs. how they’re displayed can cause surprises when the data are loaded into R.

By default `readxl` will guess the data type in a given column. A recommended workflow is to let `readxl` guess the column types, confirm that you're happy with the guessed column types, and if not, go back and re-import specifying `col_types` as shown in [Section 22.2.3](#).

Another challenge is when you have a column in your Excel spreadsheet that has a mix of these types, e.g. some cells are numeric, others text, others dates. When importing the data into R `readxl` has to make some decisions. In these cases you can set the type for this column to "list", which will load the column as a list of length 1 vectors, where the type of each element of the vector is guessed.

22.2.7 Data not in cell values

`tidyxl` is useful for importing non-tabular data from Excel files into R. For example, `tidyxl` doesn't coerce a pivot table into a data frame. See <https://nacnudus.github.io/spreadsheet-munging-strategies/> for more on strategies for working with non-tabular data from Excel.

22.2.8 Writing to Excel

Let's create a small data frame that we can then write out. Note that `item` is a factor and `quantity` is an integer.

```
bake_sale <- tibble(  
  item      = factor(c("brownie", "cupcake", "cookie")),  
  quantity  = c(10, 5, 8)  
)  
  
bake_sale  
#> # A tibble: 3 × 2  
#>   item      quantity  
#>   <fct>     <dbl>  
#> 1 brownie      10
```

```
#> 2 cupcake      5  
#> 3 cookie       8
```

You can write data back to disk as an Excel file using the `write_xlsx()` from the `writexl` package.

```
library(writexl)  
write_xlsx(bake_sale, path = "data/bake-sale.xlsx")
```

[Figure 22.4](#) shows what the data looks like in Excel. Note that column names are included and bolded. These can be turned off by setting `col_names` and `format_headers` arguments to `FALSE`.

| | A | B | C | D | E | F | G |
|---|-------------|-----------------|---|---|---|---|---|
| 1 | item | quantity | | | | | |
| 2 | brownie | 10 | | | | | |
| 3 | cupcake | 5 | | | | | |
| 4 | cookie | 8 | | | | | |
| 5 | | | | | | | |
| 6 | | | | | | | |
| 7 | | | | | | | |

Figure 22.4: Spreadsheet called `bake_sale.xlsx` in Excel.

Just like reading from a CSV, information on data type is lost when we read the data back in. This makes Excel files unreliable for caching interim results as well. For alternatives, see [Section 8.5](#).

```
read_excel("data/bake-sale.xlsx")
#> # A tibble: 3 × 2
#>   item      quantity
#>   <chr>     <dbl>
#> 1 brownie      10
#> 2 cupcake       5
#> 3 cookie        8
```

22.2.9 Formatted output

The `readxl` package is a light-weight solution for writing a simple Excel spreadsheet, but if you're interested in additional features like writing to sheets within a spreadsheet and styling, you will want to use the `openxlsx` package. Note that this package is not part of the tidyverse so the functions and workflows may feel unfamiliar. For example, function names are camelCase, multiple functions can't be composed in pipelines, and arguments are in a different order than they tend to be in the tidyverse. However, this is ok. As your R learning and usage expands outside of this book you will encounter lots of different styles used in various R packages that you might need to use to accomplish specific goals in R. A good way of familiarizing yourself with the coding style used in a new package is to run the examples provided in function documentation to get a feel for the syntax and the output formats as well as reading any vignettes that might come with the package.

Below we show how to write a spreadsheet with three sheets, one for each species of penguins in the `penguins` data frame.

```
library(openxlsx)
library(palmerpenguins)

# Create a workbook (spreadsheet)
penguins_species <- createWorkbook()
```

```
# Add three sheets to the spreadsheet
addWorksheet(penguins_species, sheetName = "Adelie")
addWorksheet(penguins_species, sheetName = "Gentoo")
addWorksheet(penguins_species, sheetName = "Chinstrap")

# Write data to each sheet
writeDataTable(
  penguins_species,
  sheet = "Adelie",
  x = penguins |> filter(species == "Adelie")
)
writeDataTable(
  penguins_species,
  sheet = "Gentoo",
  x = penguins |> filter(species == "Gentoo")
)
writeDataTable(
  penguins_species,
  sheet = "Chinstrap",
  x = penguins |> filter(species == "Chinstrap")
)
```

This creates a workbook object:

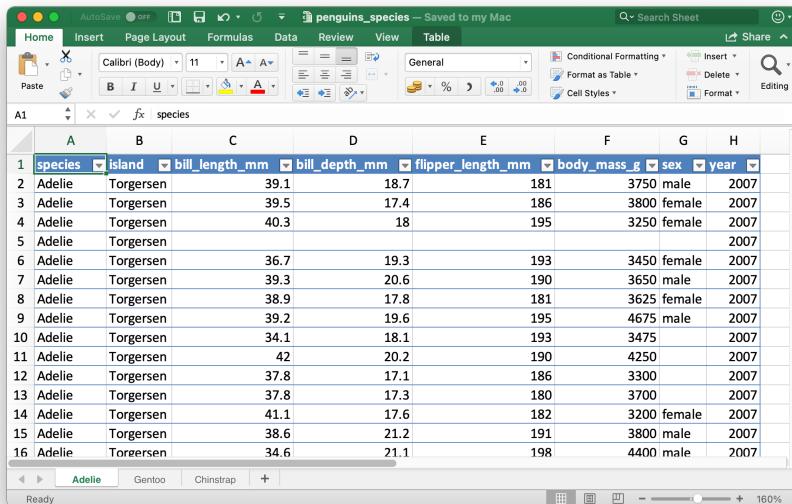

```
penguins_species
#> A Workbook object.
#>
#> Worksheets:
#>   Sheet 1: "Adelie"
#>
#>
#>   Sheet 2: "Gentoo"
#>
#>
#>   Sheet 3: "Chinstrap"
#>
```

```
#>
#>
#> Worksheet write order: 1, 2, 3
#> Active Sheet 1: "Adelie"
#> Position: 1
```

And we can write this to this with `saveWorkbook()`.

```
saveWorkbook(penguins_species, "data/penguins-species.xlsx")
```

The resulting spreadsheet is shown in [Figure 22.5](#). By default, openxlsx formats the data as an Excel table.

A screenshot of Microsoft Excel showing a table of penguin species data. The table has 16 rows and 8 columns, labeled A through H. The columns are: species, island, bill_length_mm, bill_depth_mm, flipper_length_mm, body_mass_g, sex, and year. The data includes rows for Adelie, Gentoo, and Chinstrap penguins from various islands like Torgersen, Paulet, and Livingstone. The table is styled with alternating row colors and has a header row. The Excel ribbon is visible at the top, and the status bar shows 'Ready' and '160%'. The formula bar shows 'fx species'.

| species | island | bill_length_mm | bill_depth_mm | flipper_length_mm | body_mass_g | sex | year |
|---------|-----------|----------------|---------------|-------------------|-------------|--------|------|
| Adelie | Torgersen | 39.1 | 18.7 | 181 | 3750 | male | 2007 |
| Adelie | Torgersen | 39.5 | 17.4 | 186 | 3800 | female | 2007 |
| Adelie | Torgersen | 40.3 | 18 | 195 | 3250 | female | 2007 |
| Adelie | Torgersen | | | | | | 2007 |
| Adelie | Torgersen | 36.7 | 19.3 | 193 | 3450 | female | 2007 |
| Adelie | Torgersen | 39.3 | 20.6 | 190 | 3650 | male | 2007 |
| Adelie | Torgersen | 38.9 | 17.8 | 181 | 3625 | female | 2007 |
| Adelie | Torgersen | 39.2 | 19.6 | 195 | 4675 | male | 2007 |
| Adelie | Torgersen | 34.1 | 18.1 | 193 | 3475 | | 2007 |
| Adelie | Torgersen | 42 | 20.2 | 190 | 4250 | | 2007 |
| Adelie | Torgersen | 37.8 | 17.1 | 186 | 3300 | | 2007 |
| Adelie | Torgersen | 37.8 | 17.3 | 180 | 3700 | | 2007 |
| Adelie | Torgersen | 41.1 | 17.6 | 182 | 3200 | female | 2007 |
| Adelie | Torgersen | 38.6 | 21.2 | 191 | 3800 | male | 2007 |
| Adelie | Torgersen | 34.6 | 21.1 | 198 | 4400 | male | 2007 |

Figure 22.5: Spreadsheet called penguins.xlsx in Excel.

See <https://ycphs.github.io/openxlsx/articles/Formatting.html> for an extensive discussion on further formatting functionality for data written from R to Excel with openxlsx.

22.2.10 Exercises

1. In an Excel file, create the following dataset and save it as `survey.xlsx`. Alternatively, you can download it as an Excel file from [here](#).

A spreadsheet with 3 columns (group, subgroup, and id) and 12 rows. The group column has two values: 1 (spanning 7 merged rows) and 2 (spanning 5 merged rows). The subgroup column has four values: A (spanning 3 merged rows), B (spanning 4 merged rows), A (spanning 2 merged rows), and B (spanning 3 merged rows). The id column has twelve values, numbers 1 through 12.

Then, read it into R, with `survey_id` as a character variable and `n_pets` as a numerical variable. Hint: You will need to convert “none” to 0.

```
#> # A tibble: 6 × 2
#>   survey_id n_pets
#>   <dbl>     <dbl>
#> 1 1         1     0
#> 2 2         2     1
#> 3 3         3     NA
#> 4 4         4     2
#> 5 5         5     2
#> 6 6         6     NA
```

2. In another Excel file, create the following dataset and save it as `roster.xlsx`. Alternatively, you can download it as an Excel file from [here](#).

A spreadsheet with 3 columns (group, subgroup, and id) and 12 rows. The group column has two values: 1 (spanning 7 merged rows) and 2 (spanning 5 merged rows). The subgroup column has four values: A (spanning 3 merged rows), B (spanning 4 merged rows), A (spanning 2 merged rows), and B (spanning 3 merged rows). The id column has twelve values, numbers 1 through 12.

Then, read it into R. The resulting data frame should be called `roster` and should look like the following.

```
#> # A tibble: 12 × 3
#>   group subgroup     id
#>   <dbl> <chr>      <dbl>
#> 1 1       A           1
#> 2 1       A           2
#> 3 1       A           3
#> 4 1       B           4
#> 5 1       B           5
#> 6 1       B           6
#> 7 1       B           7
#> 8 2       A           8
#> 9 2       A           9
#> 10 2      B          10
#> 11 2      B          11
#> 12 2      B          12
```

3. In a new Excel file, create the following dataset and save it as `sales.xlsx`. Alternatively, you can download it as an Excel file from [here](#).

A spreadsheet with 2 columns and 13 rows. The first two rows have text containing information about the sheet. Row 1 says "This file contains information on sales". Row 2 says "Data are organized by brand name, and for each brand, we have the ID number for the item sold, and how many are sold.". Then there are two empty rows, and then 9 rows of data.

- a. Read `sales.xlsx` in and save as `sales`. The data frame should look like the following, with `id` and `n` as column names and with 9 rows.

```
#> # A tibble: 9 × 2  
#>   id      n  
#>   <chr>    <chr>  
#> 1 Brand 1 n  
#> 2 1234     8  
#> 3 8721     2  
#> 4 1822     3  
#> 5 Brand 2 n  
#> 6 3333     1  
#> 7 2156     3  
#> 8 3987     6  
#> 9 3216     5
```

- b. Modify `sales` further to get it into the following tidy format with three columns (`brand`, `id`, and `n`) and 7 rows of data. Note that `id` and `n` are numeric, `brand` is a character variable.

```
#> # A tibble: 7 × 3  
#>   brand     id     n  
#>   <chr>    <dbl> <dbl>  
#> 1 Brand 1 1234     8  
#> 2 Brand 1 8721     2  
#> 3 Brand 1 1822     3  
#> 4 Brand 2 3333     1  
#> 5 Brand 2 2156     3  
#> 6 Brand 2 3987     6  
#> 7 Brand 2 3216     5
```

4. Recreate the `bake_sale` data frame, write it out to an Excel file using the `write.xlsx()` function from the `openxlsx` package.

5. In [Chapter 8](#) you learned about the `janitor::clean_names()` function to turn column names into snake case. Read the

`students.xlsx` file that we introduced earlier in this section and use this function to “clean” the column names.

6. What happens if you try to read in a file with `.xlsx` extension with `read_xls()`?

22.3 Google Sheets

22.3.1 Prerequisites

This section will also focus on spreadsheets, but this time you’ll be loading data from a Google Sheet with the **googlesheets4** package. This package is non-core tidyverse as well, you need to load it explicitly.

```
library(googlesheets4)  
library(tidyverse)
```

A quick note about the name of the package: googlesheets4 uses v4 of the [Sheets API v4](#) to provide an R interface to Google Sheets, hence the name.

22.3.2 Getting started

The main function of the googlesheets4 package is `read_sheet()`, which reads a Google Sheet from a URL or a file id. This function also goes by the name `range_read()`.

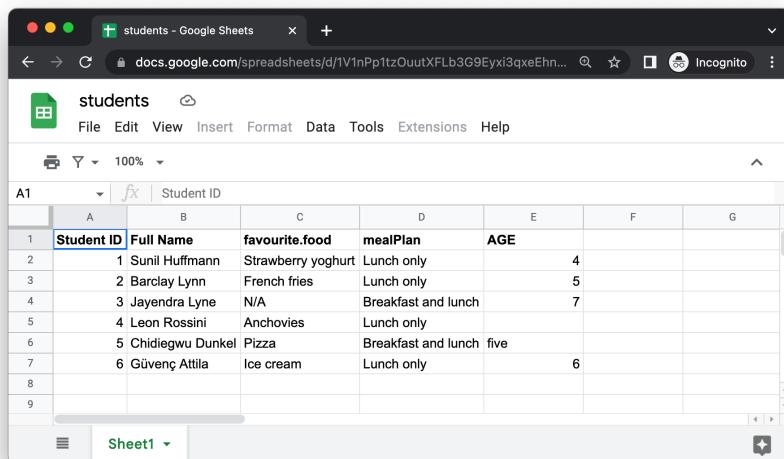

You can also create a brand new sheet with `gs4_create()` or write to an existing sheet with `sheet_write()` and friends.

In this section we’ll work with the same datasets as the ones in the Excel section to highlight similarities and differences between workflows for reading data from Excel and Google Sheets. `readxl` and `googlesheets4` packages are both designed to mimic the functionality of the `readr`

package, which provides the `read_csv()` function you've seen in [Chapter 8](#). Therefore, many of the tasks can be accomplished with simply swapping out `read_excel()` for `read_sheet()`. However you'll also see that Excel and Google Sheets don't behave in exactly the same way, therefore other tasks may require further updates to the function calls.

22.3.3 Read sheets

[Figure 22.6](#) shows what the spreadsheet we're going to read into R looks like in Google Sheets. This is the same dataset as in [Figure 22.1](#), except it's stored in a Google Sheet instead of Excel.

The screenshot shows a Google Sheets document titled "students". The spreadsheet contains data for six students across five columns: Student ID, Full Name, favourite.food, mealPlan, and AGE. The data is as follows:

| | A | B | C | D | E | F | G |
|---|------------|------------------|--------------------|---------------------|------|---|---|
| 1 | Student ID | Full Name | favourite.food | mealPlan | AGE | | |
| 2 | 1 | Sunil Huffmann | Strawberry yoghurt | Lunch only | 4 | | |
| 3 | 2 | Barclay Lynn | French fries | Lunch only | 5 | | |
| 4 | 3 | Jayendra Lyne | N/A | Breakfast and lunch | 7 | | |
| 5 | 4 | Leon Rossini | Anchovies | Lunch only | | | |
| 6 | 5 | Chidiegwu Dunkel | Pizza | Breakfast and lunch | five | | |
| 7 | 6 | Güvenç Attila | Ice cream | Lunch only | 6 | | |
| 8 | | | | | | | |
| 9 | | | | | | | |

Figure 22.6: Google Sheet called students in a browser window.

The first argument to `read_sheet()` is the URL of the file to read. You can also access this file via <https://pos.it/r4ds-students>, however note that at the time of writing this book you can't read a sheet directly from a short link.

```
students <- read_sheet("https://docs.google.com/spreadsheets/d/1V1nPp1tz0uutXcOOGJLjwvDgkzWQHdIwvPmBZGKU/edit#gid=100000000")  
#> ✓ Reading from "students".  
#> ✓ Range 'Sheet1'.
```

`read_sheet()` will read the file in as a tibble.

```
students  
#> # A tibble: 6 × 5  
#>   `Student ID` `Full Name`     favourite.food    meal_time  
#>   <dbl> <chr>           <chr>             <chr>  
#> 1      1 Sunil Huffmann  Strawberry yoghurt  Lunch  
#> 2      2 Barclay Lynn    French fries       Lunch  
#> 3      3 Jayendra Lyne   N/A                Breakfast  
#> 4      4 Leon Rossini   Anchovies        Lunch  
#> 5      5 Chidiegwu Dunkel Pizza        Brunch  
#> 6      6 Güvenç Attila   Ice cream        Lunch
```

Just like we did with `read_excel()`, we can supply column names, NA strings, and column types to `read_sheet()`.

```
students <- read_sheet(  
  "https://docs.google.com/spreadsheets/d/1V1nPp1tz0uutXcOOGJLjwvDgkzWQHdIwvPmBZGKU/edit#gid=100000000",  
  col_names = c("student_id", "full_name", "favourite_food", "meal_time", "age"),  
  skip = 1,  
  na = c("", "N/A"),  
  col_types = c("dcccc")  
) |>  
  mutate(  
    age = if_else(age == "five", "5", age),  
    age = parse_number(age)  
)
```

```
#> ✓ Reading from "students".
#> ✓ Range '2:10000000'.

students
#> # A tibble: 6 × 5
#>   student_id full_name      favourite_food    meal
#>       <dbl> <chr>          <chr>           <chr>
#> 1         1 Sunil Huffmann Strawberry yoghurt Lunc
#> 2         2 Barclay Lynn    French fries      Lunc
#> 3         3 Jayendra Lyne  <NA>             Breac
#> 4         4 Leon Rossini   Anchovies       Lunc
#> 5         5 Chidiegwu Dunkel Pizza          Breac
#> 6         6 Güvenç Attila   Ice cream       Lunc
```

Note that we defined column types a bit differently here, using short codes. For example, “dccc” stands for “double, character, character, character, character”.

It’s also possible to read individual sheets from Google Sheets as well. Let’s read the penguins Google Sheet at <https://pos.it/r4ds-penguins>, and specifically the “Torgersen Island” sheet in it.

```
read_sheet("https://docs.google.com/spreadsheets/d/1aFu8
#> ✓ Reading from "penguins".
#> ✓ Range "'Torgersen Island'".
#> # A tibble: 52 × 8
#>   species island    bill_length_mm bill_depth_mm flipper_length_mm
#>   <chr>   <chr>      <list>        <list>           <list>
#> 1 Adelie  Torgersen <dbl [1]>    <dbl [1]>        <dbl [1]>
#> 2 Adelie  Torgersen <dbl [1]>    <dbl [1]>        <dbl [1]>
#> 3 Adelie  Torgersen <dbl [1]>    <dbl [1]>        <dbl [1]>
#> 4 Adelie  Torgersen <chr [1]>    <chr [1]>        <chr [1]>
#> 5 Adelie  Torgersen <dbl [1]>    <dbl [1]>        <dbl [1]>
#> 6 Adelie  Torgersen <dbl [1]>    <dbl [1]>        <dbl [1]>
```

```
#> # ... with 46 more rows, and abbreviated variable names  
#> #   ^body_mass_g
```

You can obtain a list of all sheets within a Google Sheet with
`sheet_names()`:

```
sheet_names("https://docs.google.com/spreadsheets/d/1aFu  
#> [1] "Torgersen Island" "Biscoe Island" "Dream Islan
```

Finally, just like with `read_excel()`, we can read in a portion of a Google Sheet by defining a range in `read_sheet()`. Note that we're also using the `gs4_example()` function below to locate an example Google Sheet that comes with the `googlesheets4` package.

```
deaths_url <- gs4_example("deaths")  
deaths <- read_sheet(deaths_url, range = "A5:F15")  
#> ✓ Reading from "deaths".  
#> ✓ Range 'A5:F15'.  
deaths  
#> # A tibble: 10 × 6  
#>   Name      Profess...¹    Age  Has kids² `Date of birth`  
#>   <chr>      <chr>    <dbl> <lgl>    <dttm>  
#> 1 David Bowie  musician...  69 TRUE    1947-01-08 00:00:00  
#> 2 Carrie Fisher actor     60 TRUE    1956-10-21 00:00:00  
#> 3 Chuck Berry  musician...  90 TRUE    1926-10-18 00:00:00  
#> 4 Bill Paxton actor     61 TRUE    1955-05-17 00:00:00  
#> 5 Prince      musician...  57 TRUE    1958-06-07 00:00:00  
#> 6 Alan Rickman actor     69 FALSE   1946-02-21 00:00:00  
#> # ... with 4 more rows, and abbreviated variable names  
#> #   ^Has kids`
```

22.3.4 Write sheets

You can write from R to Google Sheets with `write_sheet()`:

```
write_sheet(bake_sale, ss = "bake-sale")
```

If you'd like to write your data to a specific (work)sheet inside a Google Sheet, you can specify that with the `sheet` argument as well.

```
write_sheet(bake_sale, ss = "bake-sale", sheet = "Sales")
```

22.3.5 Authentication

While you can read from a public Google Sheet without authenticating with your Google account, reading a private sheet or writing to a sheet requires authentication so that `googlesheets4` can view and manage *your* Google Sheets.

When you attempt to read in a sheet that requires authentication, `googlesheets4` will direct you to a web browser with a prompt to sign in to your Google account and grant permission to operate on your behalf with Google Sheets. However, if you want to specify a specific Google account, authentication scope, etc. you can do so with `gs4_auth()`, e.g. `gs4_auth(email = "mine@example.com")`, which will force the use of a token associated with a specific email. For further authentication details, we recommend reading the documentation `googlesheets4 auth vignette`:

<https://googlesheets4.tidyverse.org/articles/auth.html>.

22.3.6 Exercises

1. Read the `students` dataset from earlier in the chapter from Excel and also from Google Sheets, with no additional arguments supplied to the `read_excel()` and `read_sheet()` functions. Are the resulting data frames in R exactly the same? If not, how are they different?
2. Read the Google Sheet titled survey from <https://pos.it/r4ds-survey>, with `survey_id` as a character variable and `n_pets` as a numerical variable.
3. Read the Google Sheet titled roster from <https://pos.it/r4ds-roster>. The resulting data frame should be called `roster` and should look like the following.

```
#> # A tibble: 12 × 3
#>   group subgroup    id
#>   <dbl> <chr>      <dbl>
#> 1     1     A          1
#> 2     1     A          2
#> 3     1     A          3
#> 4     1     B          4
#> 5     1     B          5
#> 6     1     B          6
#> 7     1     B          7
#> 8     2     A          8
#> 9     2     A          9
#> 10    2     B         10
#> 11    2     B         11
#> 12    2     B         12
```

22.4 Summary

In this chapter you learned how to read data into R from spreadsheets: from Microsoft Excel with `read_excel()` from the `readxl` package and

from Google Sheets with `read_sheet()` from the `googlesheets4` package. These functions work very similarly to each other and have similar arguments for specifying column names, NA strings, rows to skip on top of the file you’re reading in, etc. Additionally, both functions make it possible to read a single sheet from a spreadsheet as well.

On the other hand, writing to an Excel file requires a different package and function (`writexl::write_xlsx()`) while you can write to a Google Sheet with the `googlesheets4` package, with `write_sheet()`.

In the next chapter, you’ll learn about a different data source and how to read data from that source into R: databases.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

(i) You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

23.1 Introduction

A huge amount of data lives in databases, so it's essential that you know how to access it. Sometimes you can ask someone to download a snapshot into a `.csv` for you, but this gets painful quickly: every time you need to make a change you'll have to communicate with another human. You want to be able to reach into the database directly to get the data you need, when you need it.

In this chapter, you'll first learn the basics of the `DBI` package: how to use it to connect to a database and then retrieve data with a SQL¹ query. **SQL**, short for **s**tructured **q**uery **l**anguage, is the lingua franca of databases, and is an important language for all data scientists to learn. That said, we're not going to start with SQL, but instead we'll teach you `dbplyr`, which can translate your `dplyr` code to the SQL. We'll use that as way to teach you some of the most important features of SQL. You won't become a SQL master by the end of the chapter, but you will be able to identify the most important components and understand what they do.

23.1.1 Prerequisites

In this chapter, we'll introduce `DBI` and `dbplyr`. `DBI` is a low-level interface that connects to databases and executes SQL; `dbplyr` is a high-level interface that translates your `dplyr` code to SQL queries then executes them with `DBI`.

```
library(DBI)
library(dbplyr)
library(tidyverse)
```

23.2 Database basics

At the simplest level, you can think about a database as a collection of data frames, called **tables** in database terminology. Like a `data.frame`, a database table is a collection of named columns, where every value in the column is the same type. There are three high level differences between data frames and database tables:

- Database tables are stored on disk and can be arbitrarily large. Data frames are stored in memory, and are fundamentally limited (although that limit is still plenty large for many problems).
- Database tables almost always have indexes. Much like the index of a book, a database index makes it possible to quickly find rows of interest without having to look at every single row. Data frames and tibbles don't have indexes, but `data.tables` do, which is one of the reasons that they're so fast.
- Most classical databases are optimized for rapidly collecting data, not analyzing existing data. These databases are called **row-oriented** because the data is stored row-by-row, rather than column-by-column like R. More recently, there's been much development of **column-oriented** databases that make analyzing the existing data much faster.

Databases are run by database management systems (**DBMS**'s for short), which come in three basic forms:

- **Client-server** DBMS's run on a powerful central server, which you connect from your computer (the client). They are great for sharing data with multiple people in an organisation. Popular client-server DBMS's include PostgreSQL, MariaDB, SQL Server, and Oracle.
- **Cloud** DBMS's, like Snowflake, Amazon's RedShift, and Google's BigQuery, are similar to client server DBMS's, but they run in the cloud. This means that they can easily handle extremely large datasets and can automatically provide more compute resources as needed.
- **In-process** DBMS's, like SQLite or `duckdb`, run entirely on your computer. They're great for working with large datasets where you're the primary user.

23.3 Connecting to a database

To connect to the database from R, you'll use a pair of packages:

- You'll always use DBI (**database interface**) because it provides a set of generic functions that connect to the database, upload data, run SQL queries, etc.

- You'll also use a package tailored for the DBMS you're connecting to. This package translates the generic DBI commands into the specifics needed for a given DBMS. There's usually one package for each DMBS, e.g. RPostgres for Postgres and RMariaDB for MySQL.

If you can't find a specific package for your DBMS, you can usually use the odbc package instead. This uses the ODBC protocol supported by many DBMS. odbc requires a little more setup because you'll also need to install an ODBC driver and tell the odbc package where to find it.

Concretely, you create a database connection using `DBI::dbConnect()`. The first argument selects the DBMS², then the second and subsequent arguments describe how to connect to it (i.e. where it lives and the credentials that you need to access it). The following code shows a couple of typical examples:

```
con <- DBI::dbConnect(  
  RMariaDB::MariaDB(),  
  username = "foo"  
)  
con <- DBI::dbConnect(  
  RPostgres::Postgres(),  
  hostname = "databases.mycompany.com",  
  port = 1234  
)
```

The precise details of the connection vary a lot from DBMS to DBMS so unfortunately we can't cover all the details here. This means you'll need to do a little research on your own. Typically you can ask the other data scientists in your team or talk to your DBA (**database administrator**). The initial setup will often take a little fiddling (and maybe some googling) to get right, but you'll generally only need to do it once.

23.3.1 In this book

Setting up a client-server or cloud DBMS would be a pain for this book, so we'll instead use an in-process DBMS that lives entirely in an R package: duckdb. Thanks to the magic of DBI, the only difference between using duckdb and any other DBMS is how you'll connect to the database. This makes it great to teach with because you can easily run this code as well as easily take what you learn and apply it elsewhere.

Connecting to duckdb is particularly simple because the defaults create a temporary database that is deleted when you quit R. That's great for learning because it guarantees

that you'll start from a clean slate every time you restart R:

```
con <- DBI::dbConnect(duckdb::duckdb())
```

duckdb is a high-performance database that's designed very much for the needs of a data scientist. We use it here because it's very easy to get started with, but it's also capable of handling gigabytes of data with great speed. If you want to use duckdb for a real data analysis project, you'll also need to supply the `dbdir` argument to make a persistent database and tell duckdb where to save it. Assuming you're using a project ([Chapter 9](#)), it's reasonable to store it in the `duckdb` directory of the current project:

```
con <- DBI::dbConnect(duckdb::duckdb(), dbdir = "duckdb")
```

23.3.2 Load some data

Since this is a new database, we need to start by adding some data. Here we'll add `mpg` and `diamonds` datasets from `ggplot2` using `DBI::dbWriteTable()`. The simplest usage of `dbWriteTable()` needs three arguments: a database connection, the name of the table to create in the database, and a data frame of data.

```
dbWriteTable(con, "mpg", ggplot2::mpg)
dbWriteTable(con, "diamonds", ggplot2::diamonds)
```

If you're using duckdb in a real project, we highly recommend learning about `duckdb_read_csv()` and `duckdb_register_arrow()`. These give you powerful and performant ways to quickly load data directly into duckdb, without having to first load it into R.

We'll also show off a useful technique for loading multiple files into a database in [Section 28.4.1](#).

23.4 DBI basics

Now that we've connected to a database with some data in it, let's perform some basic operations with DBI.

23.4.1 What's there?

The most important database objects for data scientists are tables. DBI provides two useful functions to either list all the tables in the database³ or to check if a specific table already exists:

```
dbListTables(con)
#> [1] "diamonds" "mpg"
dbExistsTable(con, "foo")
#> [1] FALSE
```

23.4.2 Extract some data

Once you've determined a table exists, you can retrieve it with `dbReadTable()`:

```
con |>
  dbReadTable("diamonds") |>
  as_tibble()
#> # A tibble: 53,940 × 10
#>   carat cut      color clarity depth table price     x     y
#>   <dbl> <fct>    <fct> <fct>   <dbl> <dbl> <dbl> <dbl> <dbl> <dbl>
#> 1  0.23 Ideal    E      SI2     61.5    55   326  3.95  3.98  2.0
#> 2  0.21 Premium  E      SI1     59.8    61   326  3.89  3.84  2.0
#> 3  0.23 Good     E      VS1     56.9    65   327  4.05  4.07  2.0
#> 4  0.29 Premium  I      VS2     62.4    58   334  4.2   4.23  2.0
#> 5  0.31 Good     J      SI2     63.3    58   335  4.34  4.35  2.0
#> 6  0.24 Very Good J      VVS2    62.8    57   336  3.94  3.96  2.0
#> # ... with 53,934 more rows
```

`dbReadTable()` returns a `data.frame` so we use `as_tibble()` to convert it into a tibble so that it prints nicely.

In real life, it's rare that you'll use `dbReadTable()` because often database tables are too big to fit in memory, and you want bring back only a subset of the rows and columns.

23.4.3 Run a query

The way you'll usually retrieve data is with `dbGetQuery()`. It takes a database connection and some SQL code and returns a data frame:

```
sql <- "
  SELECT carat, cut, clarity, color, price
  FROM diamonds
  WHERE price > 15000
"
as_tibble(dbGetQuery(con, sql))
#> # A tibble: 1,655 × 5
#>   carat     cut    clarity color  price
#>   <dbl> <fct>   <fct>   <fct> <int>
#> 1 1.54 Premium VS2      E     15002
#> 2 1.19 Ideal   VVS1     F     15005
#> 3 2.1  Premium SI1      I     15007
#> 4 1.69 Ideal   SI1      D     15011
#> 5 1.5  Very Good VVS2     G     15013
#> 6 1.73 Very Good VS1      G     15014
#> # ... with 1,649 more rows
```

Don’t worry if you’ve never seen SQL before; you’ll learn more about it shortly. But if you read it carefully, you might guess that it selects five columns of the diamonds dataset and all the rows where `price` is greater than 15,000.

You’ll need to be a little careful with `dbGetQuery()` since it can potentially return more data than you have memory. We won’t discuss it further here, but if you’re dealing with very large datasets it’s possible to deal with a “page” of data at a time by using `dbSendQuery()` to get a “result set” which you can page through by calling `dbFetch()` until `dbHasCompleted()` returns `TRUE`.

23.4.4 Other functions

There are lots of other functions in DBI that you might find useful if you’re managing your own data (like `dbWriteTable()` which we used in [Section 23.3.2](#)), but we’re going to skip past them in the interest of staying focused on working with data that already lives in a database.

23.5 dbplyr basics

Now that you’ve learned the low-level basics for connecting to a database and running a query, we’re going to switch it up a bit and learn a bit about dbplyr. dbplyr is a dplyr **backend**, which means that you keep writing dplyr code but the backend executes it

differently. In this, dbplyr translates to SQL; other backends include [dtplyr](#) which translates to [data.table](#), and [multidplyr](#) which executes your code on multiple cores.

To use dbplyr, you must first use `tbl()` to create an object that represents a database table:

```
diamonds_db <- tbl(con, "diamonds")
diamonds_db
#> # Source:   table<diamonds> [?? x 10]
#> # Database: DuckDB 0.6.2-dev1166 [unknown@Linux 5.15.0-1031-azure
#>   carat      cut    color clarity depth table price     x     y
#>   <dbl> <fct> <fct> <fct> <dbl> <dbl> <int> <dbl> <dbl> <dbl>
#> 1 0.23 Ideal    E     SI2      61.5    55    326  3.95  3.98  2...
#> 2 0.21 Premium  E     SI1      59.8    61    326  3.89  3.84  2...
#> 3 0.23 Good    E     VS1      56.9    65    327  4.05  4.07  2...
#> 4 0.29 Premium I     VS2      62.4    58    334  4.2   4.23  2...
#> 5 0.31 Good    J     SI2      63.3    58    335  4.34  4.35  2...
#> 6 0.24 Very Good J     VVS2     62.8    57    336  3.94  3.96  2...
#> # ... with more rows
```

-  There are two other common ways to interact with a database. First, many corporate databases are very large so you need some hierarchy to keep all the tables organised. In that case you might need to supply a schema, or a catalog and a schema, in order to pick the table you're interested in:

```
diamonds_db <- tbl(con, in_schema("sales", "diamonds"))
diamonds_db <- tbl(con, in_catalog("north_america", "sales", "diamonds"))
```

Other times you might want to use your own SQL query as a starting point:

```
diamonds_db <- tbl(con, sql("SELECT * FROM diamonds"))
```

This object is **lazy**; when you use dplyr verbs on it, dplyr doesn't do any work: it just records the sequence of operations that you want to perform and only performs them when needed. For example, take the following pipeline:

```
big_diamonds_db <- diamonds_db |>
  filter(price > 15000) |>
  select(carat:clarity, price)
```

```
big_diamonds_db
#> # Source: SQL [?? x 5]
#> # Database: DuckDB 0.6.2-dev1166 [unknown@Linux 5.15.0-1031-azure
#>   carat cut      color clarity price
#>   <dbl> <fct>    <fct> <fct>   <int>
#> 1 1.54 Premium E VS2 15002
#> 2 1.19 Ideal F VVS1 15005
#> 3 2.1 Premium I SI1 15007
#> 4 1.69 Ideal D SI1 15011
#> 5 1.5 Very Good G VVS2 15013
#> 6 1.73 Very Good G VS1 15014
#> # ... with more rows
```

You can tell this object represents a database query because it prints the DBMS name at the top, and while it tells you the number of columns, it typically doesn't know the number of rows. This is because finding the total number of rows usually requires executing the complete query, something we're trying to avoid.

You can see the SQL code generated by the dbplyr function `show_query()`:

```
big_diamonds_db |>
  show_query()
#> <SQL>
#> SELECT carat, cut, color, clarity, price
#> FROM diamonds
#> WHERE (price > 15000.0)
```

To get all the data back into R, you call `collect()`. Behind the scenes, this generates the SQL, calls `dbGetQuery()` to get the data, then turns the result into a tibble:

```
big_diamonds <- big_diamonds_db |>
  collect()
big_diamonds
#> # A tibble: 1,655 x 5
#>   carat cut      color clarity price
#>   <dbl> <fct>    <fct> <fct>   <int>
#> 1 1.54 Premium E VS2 15002
#> 2 1.19 Ideal F VVS1 15005
#> 3 2.1 Premium I SI1 15007
#> 4 1.69 Ideal D SI1 15011
#> 5 1.5 Very Good G VVS2 15013
```

```
#> 6 1.73 Very Good G VS1 15014  
#> # ... with 1,649 more rows
```

Typically, you'll use dbplyr to select the data you want from the database, performing basic filtering and aggregation using the translations described below. Then, once you're ready to analyse the data with functions that are unique to R, you'll `collect()` the data to get an in-memory tibble, and continue your work with pure R code.

23.6 SQL

The rest of the chapter will teach you a little SQL through the lens of dbplyr. It's a rather non-traditional introduction to SQL but we hope it will get you quickly up to speed with the basics. Luckily, if you understand dplyr you're in a great place to quickly pick up SQL because so many of the concepts are the same.

We'll explore the relationship between dplyr and SQL using a couple of old friends from the nycflights13 package: `flights` and `planes`. These datasets are easy to get into our learning database because dbplyr has a function designed for this exact scenario:

```
dbplyr::copy_nycflights13(con)  
#> Creating table: airlines  
#> Creating table: airports  
#> Creating table: flights  
#> Creating table: planes  
#> Creating table: weather  
flights <- tbl(con, "flights")  
planes <- tbl(con, "planes")
```

23.6.1 SQL basics

The top-level components of SQL are called **statements**. Common statements include `CREATE` for defining new tables, `INSERT` for adding data, and `SELECT` for retrieving data. We will focus on `SELECT` statements, also called **queries**, because they are almost exclusively what you'll use as a data scientist.

A query is made up of **clauses**. There are five important clauses: `SELECT`, `FROM`, `WHERE`, `ORDER BY`, and `GROUP BY`. Every query must have the `SELECT`⁴ and `FROM`⁵ clauses and the simplest query is `SELECT * FROM table`, which selects all columns from the specified table. This is what dbplyr generates for an unadulterated table :

```
flights |> show_query()
#> <SQL>
#> SELECT *
#> FROM flights
planes |> show_query()
#> <SQL>
#> SELECT *
#> FROM planes
```

WHERE and ORDER BY control which rows are included and how they are ordered:

```
flights |>
  filter(dest == "IAH") |>
  arrange(dep_delay) |>
  show_query()
#> <SQL>
#> SELECT *
#> FROM flights
#> WHERE (dest = 'IAH')
#> ORDER BY dep_delay
```

GROUP BY converts the query to a summary, causing aggregation to happen:

```
flights |>
  group_by(dest) |>
  summarize(dep_delay = mean(dep_delay, na.rm = TRUE)) |>
  show_query()
#> <SQL>
#> SELECT dest, AVG(dep_delay) AS dep_delay
#> FROM flights
#> GROUP BY dest
```

There are two important differences between dplyr verbs and SELECT clauses:

- In SQL, case doesn't matter: you can write `select`, `SELECT`, or even `SeLeCt`. In this book we'll stick with the common convention of writing SQL keywords in uppercase to distinguish them from table or variables names.
- In SQL, order matters: you must always write the clauses in the order `SELECT`, `FROM`, `WHERE`, `GROUP BY`, `ORDER BY`. Confusingly, this order doesn't match how the clauses actually evaluated which is first `FROM`, then `WHERE`, `GROUP BY`, `SELECT`, and `ORDER BY`.

The following sections explore each clause in more detail.

- (i) Note that while SQL is a standard, it is extremely complex and no database follows it exactly. While the main components that we'll focus on in this book are very similar between DBMSs, there are many minor variations. Fortunately, dbplyr is designed to handle this problem and generates different translations for different databases. It's not perfect, but it's continually improving, and if you hit a problem you can file an issue [on GitHub](#) to help us do better.

23.6.2 SELECT

The `SELECT` clause is the workhorse of queries and performs the same job as `select()`, `mutate()`, `rename()`, `relocate()`, and, as you'll learn in the next section, `summarize()`.

`select()`, `rename()`, and `relocate()` have very direct translations to `SELECT` as they just affect where a column appears (if at all) along with its name:

```
planes |>
  select(tailnum, type, manufacturer, model, year) |>
  show_query()
#> <SQL>
#> SELECT tailnum, "type", manufacturer, model, "year"
#> FROM planes

planes |>
  select(tailnum, type, manufacturer, model, year) |>
  rename(year_built = year) |>
  show_query()
#> <SQL>
#> SELECT tailnum, "type", manufacturer, model, "year" AS year_built
#> FROM planes

planes |>
  select(tailnum, type, manufacturer, model, year) |>
  relocate(manufacturer, model, .before = type) |>
  show_query()
#> <SQL>
#> SELECT tailnum, manufacturer, model, "type", "year"
#> FROM planes
```

This example also shows you how SQL does renaming. In SQL terminology renaming is called **aliasing** and is done with `AS`. Note that unlike `mutate()`, the old name is on the left and the new name is on the right.

- (i) In the examples above note that "year" and "type" are wrapped in double quotes. That's because these are **reserved words** in duckdb, so dbplyr quotes them to avoid any potential confusion between column/table names and SQL operators.

When working with other databases you're likely to see every variable name quoted because only a handful of client packages, like duckdb, know what all the reserved words are, so they quote everything to be safe.

```
SELECT "tailnum", "type", "manufacturer", "model", "year"  
FROM "planes"
```

Some other database systems use backticks instead of quotes:

```
SELECT `tailnum`, `type`, `manufacturer`, `model`, `year`  
FROM `planes`
```

The translations for `mutate()` are similarly straightforward: each variable becomes a new expression in `SELECT`:

```
flights |>  
  mutate(  
    speed = distance / (air_time / 60)  
  ) |>  
  show_query()  
#> <SQL>  
#> SELECT *, distance / (air_time / 60.0) AS speed  
#> FROM flights
```

We'll come back to the translation of individual components (like `/`) in [Section 23.7](#).

23.6.3 FROM

The `FROM` clause defines the data source. It's going to be rather uninteresting for a little while, because we're just using single tables. You'll see more complex examples once we hit the join functions.

23.6.4 GROUP BY

`group_by()` is translated to the `GROUP BY`⁶ clause and `summarize()` is translated to the `SELECT` clause:

```
diamonds_db |>
  group_by(cut) |>
  summarize(
    n = n(),
    avg_price = mean(price, na.rm = TRUE)
  ) |>
  show_query()
#> <SQL>
#> SELECT cut, COUNT(*) AS n, AVG(price) AS avg_price
#> FROM diamonds
#> GROUP BY cut
```

We'll come back to what's happening with translation `n()` and `mean()` in [Section 23.7](#).

23.6.5 WHERE

`filter()` is translated to the `WHERE` clause:

```
flights |>
  filter(dest == "IAH" | dest == "HOU") |>
  show_query()
#> <SQL>
#> SELECT *
#> FROM flights
#> WHERE (dest = 'IAH' OR dest = 'HOU')

flights |>
  filter(arr_delay > 0 & arr_delay < 20) |>
  show_query()
#> <SQL>
#> SELECT *
#> FROM flights
#> WHERE (arr_delay > 0.0 AND arr_delay < 20.0)
```

There are a few important details to note here:

- `|` becomes `OR` and `&` becomes `AND`.
- SQL uses `=` for comparison, not `==`. SQL doesn't have assignment, so there's no potential for confusion there.

- SQL uses only ` '' ` for strings, not ` "" `. In SQL, ` "" ` is used to identify variables, like R's ` `` `.

Another useful SQL operator is `IN`, which is very close to R's `%in%`:

```
flights |>
  filter(dest %in% c("IAH", "HOU")) |>
  show_query()
#> <SQL>
#> SELECT *
#> FROM flights
#> WHERE (dest IN ('IAH', 'HOU'))
```

SQL uses `NONE` instead of `NA`. `NONE`s behave similarly to `NA`s. The main difference is that while they're “infectious” in comparisons and arithmetic, they are silently dropped when summarizing. `dbplyr` will remind you about this behavior the first time you hit it:

```
flights |>
  group_by(dest) |>
  summarize(delay = mean(arr_delay))
#> Warning: Missing values are always removed in SQL aggregation fun
#> Use `na.rm = TRUE` to silence this warning
#> This warning is displayed once every 8 hours.
#> # Source:   SQL [?? x 2]
#> # Database: DuckDB 0.6.2-dev1166 [unknwon@Linux 5.15.0-1031-azure
#>   dest   delay
#>   <chr> <dbl>
#> 1 ORD    5.88
#> 2 FLL    8.08
#> 3 IAH    4.24
#> 4 MIA    0.299
#> 5 DCA    9.07
#> 6 SLC    0.176
#> # ... with more rows
```

If you want to learn more about how `NONE`s work, you might enjoy “[Three valued logic](#)” by Markus Winand.

In general, you can work with `NONE`s using the functions you'd use for `NA`s in R:

```
flights |>
  filter(!is.na(dep_delay)) |>
  show_query()
#> <SQL>
#> SELECT *
#> FROM flights
#> WHERE (NOT((dep_delay IS NULL)))
```

This SQL query illustrates one of the drawbacks of dbplyr: while the SQL is correct, it isn't as simple as you might write by hand. In this case, you could drop the parentheses and use a special operator that's easier to read:

WHERE "dep_delay" IS NOT NULL

Note that if you `filter()` a variable that you created using a summarize, dbplyr will generate a HAVING clause, rather than a FROM clause. This is a one of the idiosyncracies of SQL created because WHERE is evaluated before SELECT, so it needs another clause that's evaluated afterwards.

```
diamonds_db |>
  group_by(cut) |>
  summarize(n = n()) |>
  filter(n > 100) |>
  show_query()
#> <SQL>
#> SELECT cut, COUNT(*) AS n
#> FROM diamonds
#> GROUP BY cut
#> HAVING (COUNT(*) > 100.0)
```

23.6.6 ORDER BY

Ordering rows involves a straightforward translation from `arrange()` to the ORDER BY clause:

```
flights |>
  arrange(year, month, day, desc(dep_delay)) |>
  show_query()
#> <SQL>
#> SELECT *
```

```
#> FROM flights  
#> ORDER BY "year", "month", "day", dep_delay DESC
```

Notice how `desc()` is translated to `DESC`: this is one of the many dplyr functions whose name was directly inspired by SQL.

23.6.7 Subqueries

Sometimes it's not possible to translate a dplyr pipeline into a single `SELECT` statement and you need to use a subquery. A **subquery** is just a query used as a data source in the `FROM` clause, instead of the usual table.

dbplyr typically uses subqueries to work around limitations of SQL. For example, expressions in the `SELECT` clause can't refer to columns that were just created. That means that the following (silly) dplyr pipeline needs to happen in two steps: the first (inner) query computes `year1` and then the second (outer) query can compute `year2`.

```
flights |>  
  mutate(  
    year1 = year + 1,  
    year2 = year1 + 1  
  ) |>  
  show_query()  
#> <SQL>  
#> SELECT *, year1 + 1.0 AS year2  
#> FROM (  
#>   SELECT *, "year" + 1.0 AS year1  
#>   FROM flights  
#> ) q01
```

You'll also see this if you attempted to `filter()` a variable that you just created.

Remember, even though `WHERE` is written after `SELECT`, it's evaluated before it, so we need a subquery in this (silly) example:

```
flights |>  
  mutate(year1 = year + 1) |>  
  filter(year1 == 2014) |>  
  show_query()  
#> <SQL>  
#> SELECT *  
#> FROM (  
#>   SELECT *, "year" + 1.0 AS year1  
#>   FROM flights
```

```
#> ) q01  
#> WHERE (year1 = 2014.0)
```

Sometimes dbplyr will create a subquery where it's not needed because it doesn't yet know how to optimize that translation. As dbplyr improves over time, these cases will get rarer but will probably never go away.

23.6.8 Joins

If you're familiar with dplyr's joins, SQL joins are very similar. Here's a simple example:

```
flights |>  
  left_join(planes |> rename(year_built = year), by = "tailnum") |>  
  show_query()  
#> <SQL>  
#> SELECT  
#>   flights.*,  
#>   planes."year" AS year_built,  
#>   "type",  
#>   manufacturer,  
#>   model,  
#>   engines,  
#>   seats,  
#>   speed,  
#>   engine  
#> FROM flights  
#> LEFT JOIN planes  
#>   ON (flights.tailnum = planes.tailnum)
```

The main thing to notice here is the syntax: SQL joins use sub-clauses of the `FROM` clause to bring in additional tables, using `ON` to define how the tables are related.

dplyr's names for these functions are so closely connected to SQL that you can easily guess the equivalent SQL for `inner_join()`, `right_join()`, and `full_join()`:

```
SELECT flights.*, "type", manufacturer, model, engines, seats, speed  
FROM flights  
INNER JOIN planes ON (flights.tailnum = planes.tailnum)  
  
SELECT flights.*, "type", manufacturer, model, engines, seats, speed  
FROM flights  
RIGHT JOIN planes ON (flights.tailnum = planes.tailnum)
```

```
SELECT flights.* , "type" , manufacturer , model , engines , seats , speed  
FROM flights  
FULL JOIN planes ON (flights.tailnum = planes.tailnum)
```

You're likely to need many joins when working with data from a database. That's because database tables are often stored in a highly normalized form, where each "fact" is stored in a single place and to keep a complete dataset for analysis you need to navigate a complex network of tables connected by primary and foreign keys. If you hit this scenario, the [dm package](#), by Tobias Schieferdecker, Kirill Müller, and Darko Bergant, is a life saver. It can automatically determine the connections between tables using the constraints that DBAs often supply, visualize the connections so you can see what's going on, and generate the joins you need to connect one table to another.

23.6.9 Other verbs

dbplyr also translates other verbs like `distinct()`, `slice_*`(`), and intersect(), and a growing selection of tidyverse functions like pivot_longer() and pivot_wider(). The easiest way to see the full set of what's currently available is to visit the dbplyr website: https://dbplyr.tidyverse.org/reference/.`

23.6.10 Exercises

1. What is `distinct()` translated to? How about `head()`?
2. Explain what each of the following SQL queries do and try recreate them using dbplyr.

```
SELECT *  
FROM flights  
WHERE dep_delay < arr_delay  
  
SELECT *, distance / (airtime / 60) AS speed  
FROM flights
```

23.7 Function translations

So far we've focused on the big picture of how dplyr verbs are translated to the clauses of a query. Now we're going to zoom in a little and talk about the translation of the R functions that work with individual columns, e.g. what happens when you use `mean(x)` in a `summarize()`?

To help see what's going on, we'll use a couple of little helper functions that run a `summarize()` or `mutate()` and show the generated SQL. That will make it a little easier to explore a few variations and see how summaries and transformations can differ.

```
summarize_query <- function(df, ...) {  
  df |>  
    summarize(...) |>  
    show_query()  
}  
  
mutate_query <- function(df, ...) {  
  df |>  
    mutate(..., .keep = "none") |>  
    show_query()  
}
```

Let's dive in with some summaries! Looking at the code below you'll notice that some summary functions, like `mean()`, have a relatively simple translation while others, like `median()`, are much more complex. The complexity is typically higher for operations that are common in statistics but less common in databases.

```
flights |>  
  group_by(year, month, day) |>  
  summarize_query(  
    mean = mean(arr_delay, na.rm = TRUE),  
    median = median(arr_delay, na.rm = TRUE)  
  )  
#> `summarise()` has grouped output by "year" and "month". You can o  
#> using the `.groups` argument.  
#> <SQL>  
#> SELECT  
#>   "year",  
#>   "month",  
#>   "day",  
#>   AVG(arr_delay) AS mean,  
#>   PERCENTILE_CONT(0.5) WITHIN GROUP (ORDER BY arr_delay) AS media  
#> FROM flights  
#> GROUP BY "year", "month", "day"
```

The translation of summary functions becomes more complicated when you use them inside a `mutate()` because they have to turn into a window function. In SQL, you turn

an ordinary aggregation function into a window function by adding `OVER` after it:

```
flights |>
  group_by(year, month, day) |>
  mutate_query(
    mean = mean(arr_delay, na.rm = TRUE),
  )
#> <SQL>
#> SELECT
#>   "year",
#>   "month",
#>   "day",
#>   AVG(arr_delay) OVER (PARTITION BY "year", "month", "day") AS me
#> FROM flights
```

In SQL, the `GROUP BY` clause is used exclusively for summary so here you can see that the grouping has moved to the `PARTITION BY` argument to `OVER`.

Window functions include all functions that look forward or backwards, like `lead()` and `lag()`:

```
flights |>
  group_by(dest) |>
  arrange(time_hour) |>
  mutate_query(
    lead = lead(arr_delay),
    lag = lag(arr_delay)
  )
#> <SQL>
#> SELECT
#>   dest,
#>   LEAD(arr_delay, 1, NULL) OVER (PARTITION BY dest ORDER BY time_
#>   LAG(arr_delay, 1, NULL) OVER (PARTITION BY dest ORDER BY time_h
#> FROM flights
#> ORDER BY time_hour
```

Here it's important to `arrange()` the data, because SQL tables have no intrinsic order. In fact, if you don't use `arrange()` you might get the rows back in a different order

every time! Notice for window functions, the ordering information is repeated: the ORDER BY clause of the main query doesn't automatically apply to window functions.

Another important SQL function is CASE WHEN. It's used as the translation of `if_else()` and `case_when()`, the dplyr function that it directly inspired. Here's a couple of simple examples:

```
flights |>
  mutate_query(
    description = if_else(arr_delay > 0, "delayed", "on-time")
  )
#> <SQL>
#> SELECT CASE WHEN (arr_delay > 0.0) THEN 'delayed' WHEN NOT (arr_d
#> FROM flights
flights |>
  mutate_query(
    description =
      case_when(
        arr_delay < -5 ~ "early",
        arr_delay < 5 ~ "on-time",
        arr_delay >= 5 ~ "late"
      )
  )
#> <SQL>
#> SELECT CASE
#> WHEN (arr_delay < -5.0) THEN 'early'
#> WHEN (arr_delay < 5.0) THEN 'on-time'
#> WHEN (arr_delay >= 5.0) THEN 'late'
#> END AS description
#> FROM flights
```

CASE WHEN is also used for some other functions that don't have a direct translation from R to SQL. A good example of this is `cut()`:

```
flights |>
  mutate_query(
    description = cut(
      arr_delay,
      breaks = c(-Inf, -5, 5, Inf),
      labels = c("early", "on-time", "late")
    )
```

```
)  
#> <SQL>  
#> SELECT CASE  
#> WHEN (arr_delay <= -5.0) THEN 'early'  
#> WHEN (arr_delay <= 5.0) THEN 'on-time'  
#> WHEN (arr_delay > 5.0) THEN 'late'  
#> END AS description  
#> FROM flights
```

dbplyr also translates common string and date-time manipulation functions, which you can learn about in `vignette("translation-function", package = "dbplyr")`. dbplyr's translations are certainly not perfect, and there are many R functions that aren't translated yet, but dbplyr does a surprisingly good job covering the functions that you'll use most of the time.

23.8 Summary

In this chapter you learned how to access data from databases. We focused on dbplyr, a dplyr “backend” that allows you to write the dplyr code you’re familiar with, and have it be automatically translated to SQL. We used that translation to teach you a little SQL; it’s important to learn some SQL because it’s *the* most commonly used language for working with data and knowing some will it easier for you to communicate with other data folks who don’t use R. If you’ve finished this chapter and would like to learn more about SQL. We have two recommendations:

- [SQL for Data Scientists](#) by Renée M. P. Teate is an introduction to SQL designed specifically for the needs of data scientists, and includes examples of the sort of highly interconnected data you’re likely to encounter in real organisations.
- [Practical SQL](#) by Anthony DeBarros is written from the perspective of a data journalist (a data scientist specialized in telling compelling stories) and goes into more detail about getting your data into a database and running your own DBMS.

In the next chapter, we’ll learn about another dplyr backend for working with large data: arrow. Arrow is designed for working with large files on disk, and is a natural complement to databases.

1. SQL is either pronounced “s”-“q”-“l” or “sequel”.
2. Typically, this is the only function you’ll use from the client package, so we recommend using `::` to pull out that one function, rather than loading the complete

package with `library()`.

3. At least, all the tables that you have permission to see.

4. Confusingly, depending on the context, `SELECT` is either a statement or a clause. To avoid this confusion, we'll generally use `query` instead of `SELECT` statement.

5. Ok, technically, only the `SELECT` is required, since you can write queries like `SELECT 1+1` to perform basic calculations. But if you want to work with data (as you always do!) you'll also need a `FROM` clause.

6. This is no coincidence: the `dplyr` function name was inspired by the SQL clause.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, This book was built with
and Garrett Grolemund. [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

24.1 Introduction

CSV files are designed to be easily read by humans. They're a good interchange format because they're very simple and they can be read by every tool under the sun. But CSV files aren't very efficient: you have to do quite a lot of work to read the data into R. In this chapter, you'll learn about a powerful alternative: the [parquet format](#), an open standards-based format widely used by big data systems.

We'll pair parquet files with [Apache Arrow](#), a multi-language toolbox designed for efficient analysis and transport of large data sets. We'll use Apache Arrow via the [arrow package](#), which provides a dplyr backend allowing you to analyze larger-than-memory datasets using familiar dplyr syntax. As an additional benefit, arrow is extremely fast: you'll see some examples later in the chapter.

Both arrow and dbplyr provide dplyr backends, so you might wonder when to use each. In many cases, the choice is made for you, as in the data is already in a database or in parquet files, and you'll want to work with it as is. But if you're starting with your own data (perhaps CSV files), you can either load it into a database or convert it to parquet. In general, it's hard to know what will work best, so in the early stages of your

analysis we'd encourage you to try both and pick the one that works the best for you.

24.1.1 Prerequisites

In this chapter, we'll continue to use the tidyverse, particularly dplyr, but we'll pair it with the arrow package which is designed specifically for working with large data.

```
library(tidyverse)  
library(arrow)
```

Later in the chapter, we'll also see some connections between arrow and duckdb, so we'll also need dbplyr and duckdb.

```
library(dbplyr, warn.conflicts = FALSE)  
library(duckdb)  
#> Loading required package: DBI
```

24.2 Getting the data

We begin by getting a dataset worthy of these tools: a data set of item checkouts from Seattle public libraries, available online at data.seattle.gov/Community/Checkouts-by-Title/tmmm-ytt6. This dataset contains 41,389,465 rows that tell you how many times each book was checked out each month from April 2015 to October 2022.

The following code will get you a cached copy of the data. The data is a 9GB CSV file, so it will take some time to download: simply getting the data is often the first challenge!

```
dir.create("data", showWarnings = FALSE)  
url <- "https://r4ds.s3.us-west-2.amazonaws.com/seattle-
```

```
# Default timeout is 60s; bump it up to an hour
options(timeout = 60 * 60)
download.file(url, "data/seattle-library-checkouts.csv")
```

24.3 Opening a dataset

Let's start by taking a look at the data. At 9GB, this file is large enough that we probably don't want to load the whole thing into memory. A good rule of thumb is that you usually want at least twice as much memory as the size of the data, and many laptops top out at 16 Gb. This means we want to avoid `read_csv()` and instead use the `arrow::open_dataset()`:

```
# partial schema for ISBN column only
opts <- CsvConvertOptions$create(col_types = schema(ISBN

seattle_csv <- open_dataset(
  sources = "data/seattle-library-checkouts.csv",
  format = "csv",
  convert_options = opts
)
```

(Here we've had to use some relatively advanced code to parse the ISBN variable correctly: this is because the first ~83,000 rows don't contain any data so arrow guesses the wrong types. The arrow team is aware of this problem and there will hopefully be a better approach by the time you read this chapter.)

What happens when this code is run? `open_dataset()` will scan a few thousand rows to figure out the structure of the data set. Then it records what it's found and stops; it will only read further rows as you specifically request them. This metadata is what we see if we print `seattle_csv`:

```
seattle_csv
#> FileSystemDataset with 1 csv file
#> UsageClass: string
#> CheckoutType: string
#> MaterialType: string
#> CheckoutYear: int64
#> CheckoutMonth: int64
#> Checkouts: int64
#> Title: string
#> ISBN: string
#> Creator: string
#> Subjects: string
#> Publisher: string
#> PublicationYear: string
```

The first line in the output tells you that `seattle_csv` is stored locally on-disk as a single CSV file; it will only be loaded into memory as needed. The remainder of the output tells you the column type that arrow has imputed for each column.

We can see what's actually in with `glimpse()`. This reveals that there are ~41 million rows and 12 columns, and shows us a few values.

```
seattle_csv |> glimpse()
#> FileSystemDataset with 1 csv file
#> 41,389,465 rows x 12 columns
#> $ UsageClass      <string> "Physical", "Physical", "D
#> $ CheckoutType    <string> "Horizon", "Horizon", "Ove
#> $ MaterialType   <string> "BOOK", "BOOK", "EBOOK", "
```

```
#> $ CheckoutYear      <int64> 2016, 2016, 2016, 2016, 2016, 2016  
#> $ CheckoutMonth    <int64> 6, 6, 6, 6, 6, 6, 6, 6, 6, 6,  
#> $ Checkouts        <int64> 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 4,  
#> $ Title             <string> "Super rich : a guide to h  
#> $ ISBN              <string> "", "", "", "", "", "", "", ""  
#> $ Creator            <string> "Simmons, Russell", "Barcl  
#> $ Subjects           <string> "Self realization, Conduct  
#> $ Publisher          <string> "Gotham Books,", "Pyr,", "  
#> $ PublicationYear   <string> "c2011.", "2010.", "2015",
```

We can start to use this dataset with `dplyr` verbs, using `collect()` to force arrow to perform the computation and return some data. For example, this code tells us the total number of checkouts per year:

```
seattle_csv |>
  count(CheckoutYear, wt = Checkouts) |>
  arrange(CheckoutYear) |>
  collect()

#> # A tibble: 18 × 2
#>   CheckoutYear      n
#>       <int>    <int>
#> 1     2005 3798685
#> 2     2006 6599318
#> 3     2007 7126627
#> 4     2008 8438486
#> 5     2009 9135167
#> 6     2010 8608966
#> # ... with 12 more rows
```

Thanks to `arrow`, this code will work regardless of how large the underlying dataset is. But it's currently rather slow: on Hadley's computer, it took ~10s to run. That's not terrible given how much data we have, but we can make it much faster by switching to a better format.

24.4 The parquet format

To make this data easier to work with, let's switch to the parquet file format and split it up into multiple files. The following sections will first introduce you to parquet and partitioning, and then apply what we learned to the Seattle library data.

24.4.1 Advantages of parquet

Like CSV, parquet is used for rectangular data, but instead of being a text format that you can read with any file editor, it's a custom binary format designed specifically for the needs of big data. This means that:

- Parquet files are usually smaller than the equivalent CSV file. Parquet relies on [efficient encodings](#) to keep file size down, and supports file compression. This helps make parquet files fast because there's less data to move from disk to memory.
- Parquet files have a rich type system. As we talked about in [Section 8.3](#), a CSV file does not provide any information about column types. For example, a CSV reader has to guess whether "08-10-2022" should be parsed as a string or a date. In contrast, parquet files store data in a way that records the type along with the data.
- Parquet files are “column-oriented”. This means that they’re organised column-by-column, much like R’s data frame. This typically leads to better performance for data analysis tasks compared to CSV files, which are organised row-by-row.
- Parquet files are “chunked”, which makes it possible to work on different parts of the file at the same time, and, if you’re lucky, to

skip some chunks all together.

24.4.2 Partitioning

As datasets get larger and larger, storing all the data in a single file gets increasingly painful and it's often useful to split large datasets across many files. When this structuring is done intelligently, this strategy can lead to significant improvements in performance because many analyses will only require a subset of the files.

There are no hard and fast rules about how to partition your data set: the results will depend on your data, access patterns, and the systems that read the data. You're likely to need to do some experimentation before you find the ideal partitioning for your situation. As a rough guide, arrow suggests that you avoid files smaller than 20MB and larger than 2GB and avoid partitions that produce more than 10,000 files. You should also try to partition by variables that you filter by; as you'll see shortly, that allows arrow to skip a lot of work by reading only the relevant files.

24.4.3 Rewriting the Seattle library data

Let's apply these ideas to the Seattle library data to see how they play out in practice. We're going to partition by `CheckoutYear`, since it's likely some analyses will only want to look at recent data and partitioning by year yields 18 chunks of a reasonable size.

To rewrite the data we define the partition using `dplyr::group_by()` and then save the partitions to a directory with `arrow::write_dataset()`. `write_dataset()` has two important arguments: a directory where we'll create the files and the format we'll use.

```
  pq_path <- "data/seattle-library-checkouts"  
  
  seattle_csv |>  
    group_by(CheckoutYear) |>  
    write_dataset(path = pq_path, format = "parquet")
```

This takes about a minute to run; as we'll see shortly this is an initial investment that pays off by making future operations much much faster.

Let's take a look at what we just produced:

```
tibble(  
  files = list.files(pq_path, recursive = TRUE),  
  size_MB = file.size(file.path(pq_path, files)) / 1024^  
)  
#> # A tibble: 18 × 2  
#>   files                      size_MB  
#>   <chr>                     <dbl>  
#> 1 CheckoutYear=2005/part-0.parquet 109.  
#> 2 CheckoutYear=2006/part-0.parquet 164.  
#> 3 CheckoutYear=2007/part-0.parquet 178.  
#> 4 CheckoutYear=2008/part-0.parquet 195.  
#> 5 CheckoutYear=2009/part-0.parquet 214.  
#> 6 CheckoutYear=2010/part-0.parquet 222.  
#> # ... with 12 more rows
```

Our single 9GB CSV file has been rewritten into 18 parquet files. The file names use a “self-describing” convention used by the [Apache Hive](#) project. Hive-style partitions name folders with a “key=value” convention, so as you might guess, the `CheckoutYear=2005` directory contains all the data where `CheckoutYear` is 2005. Each file is between 100 and 300 MB and the total size is now around 4 GB, a little over half

the size of the original CSV file. This is as we expect since parquet is a much more efficient format.

24.5 Using dplyr with arrow

Now we've created these parquet files, we'll need to read them in again. We use `open_dataset()` again, but this time we give it a directory:

```
seattle_pq <- open_dataset(pq_path)
```

Now we can write our dplyr pipeline. For example, we could count the total number of books checked out in each month for the last five years:

```
query <- seattle_pq |>
  filter(CheckoutYear >= 2018, MaterialType == "BOOK") |>
  group_by(CheckoutYear, CheckoutMonth) |>
  summarise(TotalCheckouts = sum(Checkouts)) |>
  arrange(CheckoutYear, CheckoutMonth)
```

Writing dplyr code for arrow data is conceptually similar to dbplyr, [Chapter 23](#): you write dplyr code, which is automatically transformed into a query that the Apache Arrow C++ library understands, which is then executed when you call `collect()`. If we print out the `query` object we can see a little information about what we expect Arrow to return when the execution takes place:

```
query
#> FileSystemDataset (query)
#> CheckoutYear: int32
#> CheckoutMonth: int64
#> TotalCheckouts: int64
#>
```

```
#> * Grouped by CheckoutYear  
#> * Sorted by CheckoutYear [asc], CheckoutMonth [asc]  
#> See $.data for the source Arrow object
```

And we can get the results by calling `collect()`:

```
query |> collect()  
#> # A tibble: 58 × 3  
#> # Groups:   CheckoutYear [5]  
#>   CheckoutYear CheckoutMonth TotalCheckouts  
#>       <int>          <int>        <int>  
#> 1     2018              1        355101  
#> 2     2018              2        309813  
#> 3     2018              3        344487  
#> 4     2018              4        330988  
#> 5     2018              5        318049  
#> 6     2018              6        341825  
#> # ... with 52 more rows
```

Like dbplyr, arrow only understands some R expressions, so you may not be able to write exactly the same code you usually would. However, the list of operations and functions supported is fairly extensive and continues to grow; find a complete list of currently supported functions in `?acero`.

24.5.1 Performance

Let's take a quick look at the performance impact of switching from CSV to parquet. First, let's time how long it takes to calculate the number of books checked out in each month of 2021, when the data is stored as a single large csv:

```
seattle_csv |>  
  filter(CheckoutYear == 2021, MaterialType == "BOOK") |  
  group_by(CheckoutMonth) |>  
  summarise(TotalCheckouts = sum(Checkouts)) |>
```

```
arrange(desc(CheckoutMonth)) |>
  collect() |>
  system.time()
#>   user  system elapsed
#> 11.980   0.924 11.350
```

Now let's use our new version of the data set in which the Seattle library checkout data has been partitioned into 18 smaller parquet files:

```
seattle_pq |>
  filter(CheckoutYear == 2021, MaterialType == "BOOK") |>
  group_by(CheckoutMonth) |>
  summarise(TotalCheckouts = sum(Checkouts)) |>
  arrange(desc(CheckoutMonth)) |>
  collect() |>
  system.time()
#>   user  system elapsed
#> 0.273   0.045   0.055
```

The ~100x speedup in performance is attributable to two factors: the multi-file partitioning, and the format of individual files:

- Partitioning improves performance because this query uses `CheckoutYear == 2021` to filter the data, and arrow is smart enough to recognize that it only needs to read 1 of the 18 parquet files.
- The parquet format improves performance by storing data in a binary format that can be read more directly into memory. The column-wise format and rich metadata means that arrow only needs to read the four columns actually used in the query (`CheckoutYear`, `MaterialType`, `CheckoutMonth`, and `Checkouts`).

This massive difference in performance is why it pays off to convert large CSVs to parquet!

24.5.2 Using dbplyr with arrow

There's one last advantage of parquet and arrow — it's very easy to turn an arrow dataset into a duckdb datasource by calling

`arrow::to_duckdb()`:

```
seattle_pq |>
  to_duckdb() |>
  filter(CheckoutYear >= 2018, MaterialType == "BOOK") |>
  group_by(CheckoutYear) |>
  summarise(TotalCheckouts = sum(Checkouts)) |>
  arrange(desc(CheckoutYear)) |>
  collect()

#> Warning: Missing values are always removed in SQL agg
#> Use `na.rm = TRUE` to silence this warning
#> This warning is displayed once every 8 hours.
#> # A tibble: 5 × 2
#>   CheckoutYear TotalCheckouts
#>       <int>        <dbl>
#> 1      2022     2431502
#> 2      2021     2266438
#> 3      2020     1241999
#> 4      2019     3931688
#> 5      2018     3987569
```

The neat thing about `to_duckdb()` is that the transfer doesn't involve any memory copying, and speaks to the goals of the arrow ecosystem: enabling seamless transitions from one computing environment to another.

24.6 Summary

In this chapter, you've been given a taste of the arrow package, which provides a dplyr backend for working with large on-disk datasets. It can work with CSV files, its much much faster if you convert your data to parquet. Parquet is a binary data format that's designed specifically for data analysis on modern computers. Far fewer tools can work with parquet files compared to CSV, but it's partitioned, compressed, and columnar structure makes it much more efficient to analyze.

Next up you'll learn about your first non-rectangular data source, which you'll handle using tools provided by the tidyverse package. We'll focus on data that comes from JSON files, but the general principles apply to tree-like data regardless of its source.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

25.1 Introduction

In this chapter, you’ll learn the art of data **rectangling**, taking data that is fundamentally hierarchical, or tree-like, and converting it into a rectangular data frame made up of rows and columns. This is important because hierarchical data is surprisingly common, especially when working with data that comes from the web.

To learn about rectangling, you’ll need to first learn about lists, the data structure that makes hierarchical data possible. Then you’ll learn about two crucial `tidyverse` functions: `tidyverse::unnest_longer()` and `tidyverse::unnest_wider()`. We’ll then show you a few case studies, applying these simple functions again and again to solve real problems. We’ll finish off by talking about JSON, the most frequent source of hierarchical datasets and a common format for data exchange on the web.

25.1.1 Prerequisites

In this chapter, we’ll use many functions from `tidyverse`, a core member of the `tidyverse`. We’ll also use `repurrrsive` to provide some interesting datasets for rectangling practice, and we’ll finish by using `jsonlite` to read JSON files into R lists.

```
library(tidyverse)
library(repurrrsive)
library(jsonlite)
```

25.2 Lists

So far you've worked with data frames that contain simple vectors like integers, numbers, characters, date-times, and factors. These vectors are simple because they're homogeneous: every element is of the same data type. If you want to store elements of different types in the same vector, you'll need a **list**, which you create with `list()`:

```
x1 <- list(1:4, "a", TRUE)
x1
#> [[1]]
#> [1] 1 2 3 4
#
#> [[2]]
#> [1] "a"
#
#> [[3]]
#> [1] TRUE
```

It's often convenient to name the components, or **children**, of a list, which you can do in the same way as naming the columns of a tibble:

```
x2 <- list(a = 1:2, b = 1:3, c = 1:4)
x2
#> $a
#> [1] 1 2
#
#> $b
#> [1] 1 2 3
```

```
#>  
#> $c  
#> [1] 1 2 3 4
```

Even for these very simple lists, printing takes up quite a lot of space. A useful alternative is `str()`, which generates a compact display of the **structure**, de-emphasizing the contents:

```
str(x1)  
#> List of 3  
#> $ : int [1:4] 1 2 3 4  
#> $ : chr "a"  
#> $ : logi TRUE  
str(x2)  
#> List of 3  
#> $ a: int [1:2] 1 2  
#> $ b: int [1:3] 1 2 3  
#> $ c: int [1:4] 1 2 3 4
```

As you can see, `str()` displays each child of the list on its own line. It displays the name, if present, then an abbreviation of the type, then the first few values.

25.2.1 Hierarchy

Lists can contain any type of object, including other lists. This makes them suitable for representing hierarchical (tree-like) structures:

```
x3 <- list(list(1, 2), list(3, 4))  
str(x3)  
#> List of 2  
#> $ :List of 2  
#>   ..$ : num 1  
#>   ..$ : num 2  
#> $ :List of 2
```

```
#> ..$ : num 3  
#> ..$ : num 4
```

This is notably different to `c()`, which generates a flat vector:

```
c(c(1, 2), c(3, 4))  
#> [1] 1 2 3 4  
  
x4 <- c(list(1, 2), list(3, 4))  
str(x4)  
#> List of 4  
#> $ : num 1  
#> $ : num 2  
#> $ : num 3  
#> $ : num 4
```

As lists get more complex, `str()` gets more useful, as it lets you see the hierarchy at a glance:

```
x5 <- list(1, list(2, list(3, list(4, list(5)))))  
str(x5)  
#> List of 2  
#> $ : num 1  
#> $ :List of 2  
#> ..$ : num 2  
#> ..$ :List of 2  
#> ...$ : num 3  
#> ...$ :List of 2  
#> ....$ : num 4  
#> ....$ :List of 1  
#> .....$ : num 5
```

As lists get even larger and more complex, `str()` eventually starts to fail, and you'll need to switch to `View()`. Figure 25.1 shows the result of calling `View(x4)`. The viewer starts by showing just the top level of the list, but you can interactively expand any of the components to see

more, as in [Figure 25.2](#). RStudio will also show you the code you need to access that element, as in [Figure 25.3](#). We'll come back to how this code works in [Section 29.2](#).

The screenshot shows the RStudio Source Editor interface with a title bar "r4ds - main - RStudio Source Editor". Below the title bar is a toolbar with icons for search, refresh, and other functions. A search bar contains the text "x4". To the right of the search bar is a "Show Attributes" button. The main area is a table viewer titled "x4". The table has three columns: "Name", "Type", and "Value". There are two rows in the table:

| Name | Type | Value |
|---------|------------|------------------|
| • x4 | list [2] | List of length 2 |
| [[1]] | double [1] | 1 |
| • [[2]] | list [2] | List of length 2 |

The row for "[[2]]" is currently selected, indicated by a blue selection bar at the bottom of the table. The entire table is enclosed in a scrollable window.

Figure 25.1: The RStudio view lets you interactively explore a complex list. The viewer opens showing only the top level of the list.

r4ds - main - RStudio Source Editor

| Name | Type | Value |
|-------|------------|------------------|
| x4 | list [2] | List of length 2 |
| [[1]] | double [1] | 1 |
| [[2]] | list [2] | List of length 2 |
| [[1]] | double [1] | 2 |
| [[2]] | list [2] | List of length 2 |

x4

Figure 25.2: Clicking on the rightward facing triangle expands that component of the list so that you can also see its children.

r4ds - main - RStudio Source Editor

| Name | Type | Value |
|-------|------------|------------------|
| x4 | list [2] | List of length 2 |
| [[1]] | double [1] | 1 |
| [[2]] | list [2] | List of length 2 |
| [[1]] | double [1] | 2 |
| [[2]] | list [2] | List of length 2 |
| [[1]] | double [1] | 3 |
| [[2]] | list [2] | List of length 2 |

x4[[2]][[2]][[2]][[2]]

Figure 25.3: You can repeat this operation as many times as needed to get to the data you’re interested in. Note the bottom-left corner: if you click an element of the list, RStudio will give you the subsetting code needed to access it, in this case `x4[[2]][[2]][[2]]`.

25.2.2 List-columns

Lists can also live inside a tibble, where we call them list-columns. List-columns are useful because they allow you to place objects in a tibble that wouldn't usually belong in there. In particular, list-columns are used a lot in the [tidymodels](#) ecosystem, because they allow you to store things like model outputs or resamples in a data frame.

Here's a simple example of a list-column:

```
df <- tibble(  
  x = 1:2,  
  y = c("a", "b"),  
  z = list(list(1, 2), list(3, 4, 5))  
)  
df  
#> # A tibble: 2 × 3  
#>       x     y     z  
#>   <int> <chr> <list>  
#> 1     1     a     <list [2]>  
#> 2     2     b     <list [3]>
```

There's nothing special about lists in a tibble; they behave like any other column:

```
df |>  
  filter(x == 1)  
#> # A tibble: 1 × 3  
#>       x     y     z  
#>   <int> <chr> <list>  
#> 1     1     a     <list [2]>
```

Computing with list-columns is harder, but that's because computing with lists is harder in general; we'll come back to that in [Chapter 28](#). In

this chapter, we'll focus on unnesting list-columns out into regular variables so you can use your existing tools on them.

The default print method just displays a rough summary of the contents. The list column could be arbitrarily complex, so there's no good way to print it. If you want to see it, you'll need to pull the list-column out and apply one of the techniques that you've learned above:

```
df |>  
  filter(x == 1) |>  
  pull(z) |>  
  str()  
#> List of 1  
#> $ :List of 2  
#>   ..$ : num 1  
#>   ..$ : num 2
```

Similarly, if you `View()` a data frame in RStudio, you'll get the standard tabular view, which doesn't allow you to selectively expand list columns. To explore those fields you'll need to `pull()` and view, e.g. `df |> pull(z) |> View()`.

Base R

It's possible to put a list in a column of a `data.frame`, but it's a lot fiddlier because `data.frame()` treats a list as a list of columns:

```
data.frame(x = list(1:3, 3:5))  
#>   x.1.3 x.3.5  
#> 1      1      3  
#> 2      2      4  
#> 3      3      5
```

You can force `data.frame()` to treat a list as a list of rows by wrapping it in list `I()`, but the result doesn't print particularly well:

```
data.frame(  
  x = I(list(1:2, 3:5)),  
  y = c("1, 2", "3, 4, 5")  
)  
#>      x      y  
#> 1 1, 2 1, 2  
#> 2 3, 4, 5 3, 4, 5
```

It's easier to use list-columns with tibbles because `tibble()` treats lists like vectors and the print method has been designed with lists in mind.

25.3 Unnesting

Now that you've learned the basics of lists and list-columns, let's explore how you can turn them back into regular rows and columns. Here we'll use very simple sample data so you can get the basic idea; in the next section we'll switch to real data.

List-columns tend to come in two basic forms: named and unnamed. When the children are **named**, they tend to have the same names in every row. For example, in `df1`, every element of list-column `y` has two elements named `a` and `b`. Named list-columns naturally unnest into columns: each named element becomes a new named column.

```
df1 <- tribble(  
  ~x, ~y,  
  1, list(a = 11, b = 12),  
  2, list(a = 21, b = 22),  
  3, list(a = 31, b = 32),  
)
```

When the children are **unnamed**, the number of elements tends to vary from row-to-row. For example, in `df2`, the elements of list-column `y` are unnamed and vary in length from one to three. Unnamed list-columns naturally unnest into rows: you'll get one row for each child.

```
df2 <- tribble(  
  ~x, ~y,  
  1, list(11, 12, 13),  
  2, list(21),  
  3, list(31, 32),  
)
```

tidy provides two functions for these two cases: `unnest_wider()` and `unnest_longer()`. The following sections explain how they work.

25.3.1 `unnest_wider()`

When each row has the same number of elements with the same names, like `df1`, it's natural to put each component into its own column with `unnest_wider()`:

```
df1 |>  
  unnest_wider(y)  
#> # A tibble: 3 × 3  
#>   x     a     b  
#>   <dbl> <dbl> <dbl>  
#> 1     1    11    12  
#> 2     2    21    22  
#> 3     3    31    32
```

By default, the names of the new columns come exclusively from the names of the list elements, but you can use the `names_sep` argument

to request that they combine the column name and the element name. This is useful for disambiguating repeated names.

```
df1 |>  
  unnest_wider(y, names_sep = "_")  
#> # A tibble: 3 × 3  
#>   x     y_a     y_b  
#>   <dbl> <dbl> <dbl>  
#> 1     1     11     12  
#> 2     2     21     22  
#> 3     3     31     32
```

We can also use `unnest_wider()` with unnamed list-columns, as in `df2`. Since columns require names but the list lacks them, `unnest_wider()` will label them with consecutive integers:

```
df2 |>  
  unnest_wider(y, names_sep = "_")  
#> # A tibble: 3 × 4  
#>   x     y_1     y_2     y_3  
#>   <dbl> <dbl> <dbl> <dbl>  
#> 1     1     11     12     13  
#> 2     2     21     NA     NA  
#> 3     3     31     32     NA
```

You'll notice that `unnest_wider()`, much like `pivot_wider()`, turns implicit missing values in to explicit missing values.

25.3.2 `unnest_longer()`

When each row contains an unnamed list, it's most natural to put each element into its own row with `unnest_longer()`:

```
df2 |>  
  unnest_longer(y)
```

```
#> # A tibble: 6 × 2
#>       x     y
#>   <dbl> <dbl>
#> 1     1    11
#> 2     1    12
#> 3     1    13
#> 4     2    21
#> 5     3    31
#> 6     3    32
```

Note how `x` is duplicated for each element inside of `y`: we get one row of output for each element inside the list-column. But what happens if one of the elements is empty, as in the following example?

```
df6 <- tribble(
  ~x, ~y,
  "a", list(1, 2),
  "b", list(3),
  "c", list()
)
df6 |> unnest_longer(y)
#> # A tibble: 3 × 2
#>       x     y
#>   <chr> <dbl>
#> 1 a         1
#> 2 a         2
#> 3 b         3
```

We get zero rows in the output, so the row effectively disappears. Once <https://github.com/tidyverse/tidyr/issues/1339> is fixed, you'll be able to keep this row, replacing `y` with `NA` by setting `keep_empty = TRUE`.

You can also unnest named list-columns, like `df1$y`, into rows. Because the elements are named, and those names might be useful data, `tidyr` puts them in a new column with the suffix `_id`:

```
df1 |>
  unnest_longer(y)
#> # A tibble: 6 × 3
#>   x     y y_id
#>   <dbl> <dbl> <chr>
#> 1 1     11  a
#> 2 1     12  b
#> 3 2     21  a
#> 4 2     22  b
#> 5 3     31  a
#> 6 3     32  b
```

If you don't want these `ids`, you can suppress them with `indices_include = FALSE`. On the other hand, sometimes the positions of the elements is meaningful, and even if the elements are unnamed, you might still want to track their indices. You can do this with `indices_include = TRUE`:

```
df2 |>
  unnest_longer(y, indices_include = TRUE)
#> # A tibble: 6 × 3
#>   x     y y_id
#>   <dbl> <dbl> <int>
#> 1 1     11     1
#> 2 1     12     2
#> 3 1     13     3
#> 4 2     21     1
#> 5 3     31     1
#> 6 3     32     2
```

25.3.3 Inconsistent types

What happens if you unnest a list-column that contains different types of vector? For example, take the following dataset where the list-column `y`

contains two numbers, a factor, and a logical, which can't normally be mixed in a single column.

```
df4 <- tribble(  
  ~x, ~y,  
  "a", list(1, "a"),  
  "b", list(TRUE, factor("a"), 5)  
)
```

`unnest_longer()` always keeps the set of columns unchanged, while changing the number of rows. So what happens? How does `unnest_longer()` produce five rows while keeping everything in `y`?

```
df4 |>  
  unnest_longer(y)  
#> # A tibble: 5 × 2  
#>   x     y  
#>   <chr> <list>  
#> 1 a     <dbl [1]>  
#> 2 a     <chr [1]>  
#> 3 b     <lgl [1]>  
#> 4 b     <fct [1]>  
#> 5 b     <dbl [1]>
```

As you can see, the output contains a list-column, but every element of the list-column contains a single element. Because `unnest_longer()` can't find a common type of vector, it keeps the original types in a list-column. You might wonder if this breaks the commandment that every element of a column must be the same type — not quite: every element is still a list, even though the contents of each element is a different type.

What happens if you find this problem in a dataset you're trying to rectangle? There are two basic options. You could use the `transform`

argument to coerce all inputs to a common type. However, it's not particularly useful here because there's only really one class that these five class can be converted to character.

```
df4 |>
  unnest_longer(y, transform = as.character)
#> # A tibble: 5 × 2
#>   x     y
#>   <chr> <chr>
#> 1 a     1
#> 2 a     a
#> 3 b     TRUE
#> 4 b     a
#> 5 b     5
```

Another option would be to filter down to the rows that have values of a specific type:

```
df4 |>
  unnest_longer(y) |>
  filter(map_lgl(y, is.numeric))
#> # A tibble: 2 × 2
#>   x     y
#>   <chr> <list>
#> 1 a     <dbl [1]>
#> 2 b     <dbl [1]>
```

Then you can call `unnest_longer()` once more. This gives us a rectangular dataset of just the numeric values.

```
df4 |>
  unnest_longer(y) |>
  filter(map_lgl(y, is.numeric)) |>
  unnest_longer(y)
#> # A tibble: 2 × 2
```

```
#>   x          y  
#> <chr> <dbl>  
#> 1 a          1  
#> 2 b          5
```

You'll learn more about `map_lgl()` in [Chapter 28](#).

25.3.4 Other functions

tidy has a few other useful rectangling functions that we're not going to cover in this book:

- `unnest_auto()` automatically picks between `unnest_longer()` and `unnest_wider()` based on the structure of the list-column.
It's great for rapid exploration, but ultimately it's a bad idea because it doesn't force you to understand how your data is structured, and makes your code harder to understand.
- `unnest()` expands both rows and columns. It's useful when you have a list-column that contains a 2d structure like a data frame, which you don't see in this book, but you might encounter if you use the [tidymodels](#) ecosystem.
- `hoist()` allows you to reach into a deeply nested list and extract just the components that you need. It's mostly equivalent to repeated invocations of `unnest_wider() + select()` so read up on it if you're trying to extract just a couple of important variables embedded in a bunch of data that you don't care about.

These functions are good to know about as you might encounter them when reading other people's code or tackling rarer rectangling challenges yourself.

25.3.5 Exercises

1. From time-to-time you encounter data frames with multiple list-columns with aligned values. For example, in the following data

frame, the values of `y` and `z` are aligned (i.e. `y` and `z` will always have the same length within a row, and the first value of `y` corresponds to the first value of `z`). What happens if you apply two `unnest_longer()` calls to this data frame? How can you preserve the relationship between `x` and `y`? (Hint: carefully read the docs).

```
df4 <- tribble(  
  ~x, ~y, ~z,  
  "a", list("y-a-1", "y-a-2"), list("z-a-1", "z-a-2")  
  "b", list("y-b-1", "y-b-2", "y-b-3"), list("z-b-1")  
)
```

25.4 Case studies

The main difference between the simple examples we used above and real data is that real data typically contains multiple levels of nesting that require multiple calls to `unnest_longer()` and/or `unnest_wider()`. This section will work through four real rectangling challenges using datasets from the repurrrsive package, inspired by datasets that we've encountered in the wild.

25.4.1 Very wide data

We'll start with `gh_repos`. This is a list that contains data about a collection of GitHub repositories retrieved using the GitHub API. It's a very deeply nested list so it's difficult to show the structure in this book; we recommend exploring a little on your own with `View(gh_repos)` before we continue.

`gh_repos` is a list, but our tools work with list-columns, so we'll begin by putting it into a tibble. We call the column `json` for reasons we'll get

to later.

```
repos <- tibble(json = gh_repos)
repos
#> # A tibble: 6 × 1
#>   json
#>   <list>
#> 1 <list [30]>
#> 2 <list [30]>
#> 3 <list [30]>
#> 4 <list [26]>
#> 5 <list [30]>
#> 6 <list [30]>
```

This tibble contains 6 rows, one row for each child of `gh_repos`. Each row contains a unnamed list with either 26 or 30 rows. Since these are unnamed, we'll start with `unnest_longer()` to put each child in its own row:

```
repos |>
  unnest_longer(json)
#> # A tibble: 176 × 1
#>   json
#>   <list>
#> 1 <named list [68]>
#> 2 <named list [68]>
#> 3 <named list [68]>
#> 4 <named list [68]>
#> 5 <named list [68]>
#> 6 <named list [68]>
#> # ... with 170 more rows
```

At first glance, it might seem like we haven't improved the situation: while we have more rows (176 instead of 6) each element of `json` is still a list. However, there's an important difference: now each element is a

named list so we can use `unnest_wider()` to put each element into its own column:

```
repos |>
  unnest_longer(json) |>
  unnest_wider(json)
#> # A tibble: 176 × 68
#>   id name      full_...¹ owner      private ht...
#>   <int> <chr>    <chr>     <list>    <lgl>  <ch...
#> 1 61160198 after    gaborc... <named list> FALSE   ht...
#> 2 40500181 argufy   gaborc... <named list> FALSE   ht...
#> 3 36442442 ask      gaborc... <named list> FALSE   ht...
#> 4 34924886 baseimpo... gaborc... <named list> FALSE   ht...
#> 5 61620661 citest    gaborc... <named list> FALSE   ht...
#> 6 33907457 clisympo... gaborc... <named list> FALSE   ht...
#> # ... with 170 more rows, 59 more variables: forks_url
#> #   collaborators_url <chr>, teams_url <chr>, hooks_u...
#> #   issue_events_url <chr>, events_url <chr>, assigne...
#> #   branches_url <chr>, tags_url <chr>, blobs_url <ch...
#> #   git_refs_url <chr>, trees_url <chr>, statuses_url...
#> #   languages_url <chr>, stargazers_url <chr>, contri...
#> #   subscribers_url <chr>, subscription_url <chr>, co...
```

This has worked but the result is a little overwhelming: there are so many columns that tibble doesn't even print all of them! We can see them all with `names()`:

```
repos |>
  unnest_longer(json) |>
  unnest_wider(json) |>
  names()
#> [1] "id"                  "name"                "full_na...
#> [4] "owner"               "private"              "html_ur...
#> [7] "description"         "fork"                 "url"
```

```

#> [10] "forks_url"           "keys_url"           "collabc
#> [13] "teams_url"          "hooks_url"          "issue_€
#> [16] "events_url"         "assignees_url"      "branch€
#> [19] "tags_url"           "blobs_url"          "git_tag
#> [22] "git_refs_url"       "trees_url"          "status€
#> [25] "languages_url"      "stargazers_url"     "contrib
#> [28] "subscribers_url"    "subscription_url"   "commits
#> [31] "git_commits_url"    "comments_url"       "issue_c
#> [34] "contents_url"       "compare_url"        "merges_
#> [37] "archive_url"        "downloads_url"      "issues_
#> [40] "pulls_url"          "milestones_url"     "notific
#> [43] "labels_url"         "releases_url"       "deploym
#> [46] "created_at"         "updated_at"         "pushed_
#> [49] "git_url"             "ssh_url"            "clone_u
#> [52] "svn_url"             "homepage"          "size"
#> [55] "stargazers_count"   "watchers_count"     "languag
#> [58] "has_issues"          "has_downloads"      "has_wik
#> [61] "has_pages"           "forks_count"        "mirror_
#> [64] "open_issues_count"   "forks"              "open_is
#> [67] "watchers"            "default_branch"    ""

```

Let's select a few that look interesting:

```

repos |>
  unnest_longer(json) |>
  unnest_wider(json) |>
  select(id, full_name, owner, description)
#> # A tibble: 176 × 4
#>       id full_name          owner
#>   <int> <chr>            <list>
#> 1 61160198 gaborcsardi/after <named list [17]>
#> 2 40500181 gaborcsardi/argufy <named list [17]>
#> 3 36442442 gaborcsardi/ask   <named list [17]>
#> 4 34924886 gaborcsardi/baseimports <named list [17]>
#> 5 61620661 gaborcsardi/citest <named list [17]>

```

```
#> 6 33907457 gaborcsardi/clisymbols <named list [17]>
#> # ... with 170 more rows
```

You can use this to work back to understand how `gh_repos` was structured: each child was a GitHub user containing a list of up to 30 GitHub repositories that they created.

`owner` is another list-column, and since it contains a named list, we can use `unnest_wider()` to get at the values:

```
repos |>
  unnest_longer(json) |>
  unnest_wider(json) |>
  select(id, full_name, owner, description) |>
  unnest_wider(owner)
#> Error in `unnest_wider()`:
#> ! Can't duplicate names between the affected columns
#>   data.
#> ✘ These names are duplicated:
#>   i `id`, from `owner`.
#> i Use `names_sep` to disambiguate using the column name.
#> i Or use `names_repair` to specify a repair strategy.
```

Uh oh, this list column also contains an `id` column and we can't have two `id` columns in the same data frame. Rather than following the advice to use `names_repair` (which would also work), we'll instead use `names_sep`:

```
repos |>
  unnest_longer(json) |>
  unnest_wider(json) |>
  select(id, full_name, owner, description) |>
  unnest_wider(owner, names_sep = "_")
```

```
#> # A tibble: 176 × 20
#>       id full_name   owner...¹ owner...² owner...³ owner...⁴
#>       <int> <chr>      <chr>      <int> <chr>      <chr>
#> 1 61160198 gaborcsar... gaborc...  660288 https://... ""
#> 2 40500181 gaborcsar... gaborc...  660288 https://... ""
#> 3 36442442 gaborcsar... gaborc...  660288 https://... ""
#> 4 34924886 gaborcsar... gaborc...  660288 https://... ""
#> 5 61620661 gaborcsar... gaborc...  660288 https://... ""
#> 6 33907457 gaborcsar... gaborc...  660288 https://... ""
#> # ... with 170 more rows, 11 more variables: owner_foll...
#> #   owner_gists_url <chr>, owner_starred_url <chr>,
#> #   owner_subscriptions_url <chr>, owner_organization...
#> #   owner_repos_url <chr>, owner_events_url <chr>,
#> #   owner_received_events_url <chr>, owner_type <chr>
#> #   owner_site_admin <lgl>, description <chr>, and at
#> #   names ¹owner_login, ²owner_id, ³owner_avatar_url,
```

This gives another wide dataset, but you can see that `owner` appears to contain a lot of additional data about the person who “owns” the repository.

25.4.2 Relational data

Nested data is sometimes used to represent data that we’d usually spread out into multiple data frames. For example, take `got_chars` which contains data about characters that appear in Game of Thrones. Like `gh_repos` it’s a list, so we start by turning it into a list-column of a tibble:

```
chars <- tibble(json = got_chars)
chars
#> # A tibble: 30 × 1
#>   json
#>   <list>
#> 1 <named list [18]>
```

```
#> 2 <named list [18]>
#> 3 <named list [18]>
#> 4 <named list [18]>
#> 5 <named list [18]>
#> 6 <named list [18]>
#> # ... with 24 more rows
```

The `json` column contains named elements, so we'll start by widening it:

```
chars |>
  unnest_wider(json)
#> # A tibble: 30 × 18
#>   url      id name gender culture born died alive
#>   <chr>    <int> <chr> <chr> <chr> <chr> <chr> <lg
#> 1 https://... 1022 Theo... Male "Ironb..." "In ..."" TRL
#> 2 https://... 1052 Tyri... Male "" "In ..."" TRL
#> 3 https://... 1074 Vict... Male "Ironb..." "In ..."" TRL
#> 4 https://... 1109 Will  Male "" "" "In ... FAL
#> 5 https://... 1166 Areo... Male "Norvo..." "In ..."" TRL
#> 6 https://... 1267 Chett Male "" "At ... "In ... FAL
#> # ... with 24 more rows, and 7 more variables: mother <
#> #   allegiances <list>, books <list>, povBooks <list>
#> #   playedBy <list>
```

And selecting a few columns to make it easier to read:

```
characters <- chars |>
  unnest_wider(json) |>
  select(id, name, gender, culture, born, died, alive)
characters
#> # A tibble: 30 × 7
#>   id name           gender culture   born
#>   <int> <chr> <chr> <chr> <chr>
#> 1 1022 Theon Greyjoy Male "Ironborn" "In 278 A
```

```
#> 2 1052 Tyrion Lannister Male   ""      "In 273 A
#> 3 1074 Victarion Greyjoy Male "Ironborn" "In 268 A
#> 4 1109 Will                 Male   ""      ""
#> 5 1166 Areo Hotah          Male   "Norvoshi" "In 257 A
#> 6 1267 Chett               Male   ""      "At Hag's
#> # ... with 24 more rows
```

There are also many list-columns:

```
chars |>
  unnest_wider(json) |>
  select(id, where(is.list))
#> # A tibble: 30 × 8
#>   id titles    aliases allegiances books      pc
#>   <int> <list>    <list>   <list>    <list>    <l
#> 1 1022 <chr [2]> <chr [4]> <chr [1]> <chr [3]> <c
#> 2 1052 <chr [2]> <chr [11]> <chr [1]> <chr [2]> <c
#> 3 1074 <chr [2]> <chr [1]> <chr [1]> <chr [3]> <c
#> 4 1109 <chr [1]> <chr [1]> <NULL>     <chr [1]> <c
#> 5 1166 <chr [1]> <chr [1]> <chr [1]> <chr [3]> <c
#> 6 1267 <chr [1]> <chr [1]> <NULL>     <chr [2]> <c
#> # ... with 24 more rows, and abbreviated variable name
```

Lets explore the `titles` column. It's an unnamed list-column, so we'll unnest it into rows:

```
chars |>
  unnest_wider(json) |>
  select(id, titles) |>
  unnest_longer(titles)
#> # A tibble: 59 × 2
#>   id titles
#>   <int> <chr>
```

```
#> 1 1022 Prince of Winterfell  
#> 2 1022 Lord of the Iron Islands (by law of the green  
#> 3 1052 Acting Hand of the King (former)  
#> 4 1052 Master of Coin (former)  
#> 5 1074 Lord Captain of the Iron Fleet  
#> 6 1074 Master of the Iron Victory  
#> # ... with 53 more rows
```

You might expect to see this data in its own table because it would be easy to join to the characters data as needed. To do so, we'll do a little cleaning: removing the rows containing empty strings and renaming titles to title since each row now only contains a single title.

```
titles <- chars |>  
  unnest_wider(json) |>  
  select(id, titles) |>  
  unnest_longer(titles) |>  
  filter(titles != "") |>  
  rename(title = titles)  
  
titles  
#> # A tibble: 52 × 2  
#>     id   title  
#>     <int> <chr>  
#> 1 1022 Prince of Winterfell  
#> 2 1022 Lord of the Iron Islands (by law of the green  
#> 3 1052 Acting Hand of the King (former)  
#> 4 1052 Master of Coin (former)  
#> 5 1074 Lord Captain of the Iron Fleet  
#> 6 1074 Master of the Iron Victory  
#> # ... with 46 more rows
```

Now, for example, we could use this table to find all the characters that are captains and see all their titles:

```
captains <- titles |> filter(str_detect(title, "Captain")
captains
#> # A tibble: 4 × 2
#>     id title
#>   <int> <chr>
#> 1 1074 Lord Captain of the Iron Fleet
#> 2 1166 Captain of the Guard at Sunspear
#> 3 150  Captain of the Black Wind
#> 4 60   Captain of the Golden Storm (formerly)

characters |>
  select(id, name) |>
  inner_join(titles, by = "id", multiple = "all")
#> # A tibble: 52 × 3
#>     id name          title
#>   <int> <chr>        <chr>
#> 1 1022 Theon Greyjoy    Prince of Winterfell
#> 2 1022 Theon Greyjoy    Lord of the Iron Islands (k
#> 3 1052 Tyrion Lannister Acting Hand of the King (f
#> 4 1052 Tyrion Lannister Master of Coin (former)
#> 5 1074 Victarion Greyjoy Lord Captain of the Iron Fl
#> 6 1074 Victarion Greyjoy Master of the Iron Victory
#> # ... with 46 more rows
```

You could imagine creating a table like this for each of the list-columns, then using joins to combine them with the character data as you need it.

25.4.3 A dash of text analysis

Sticking with the same data, what if we wanted to find the most common words in the title? One simple approach starts by using `str_split()` to break each element of `title` up into words by splitting on " ":

```
titles |>
  mutate(word = str_split(title, " "), .keep = "unused")
#> # A tibble: 52 × 2
#>   id word
#>   <int> <list>
#> 1 1022 <chr [3]>
#> 2 1022 <chr [11]>
#> 3 1052 <chr [6]>
#> 4 1052 <chr [4]>
#> 5 1074 <chr [6]>
#> 6 1074 <chr [5]>
#> # ... with 46 more rows
```

This creates an unnamed variable length list-column, so we can use unnest_longer():

```
titles |>
  mutate(word = str_split(title, " "), .keep = "unused")
  unnest_longer(word)
#> # A tibble: 198 × 2
#>   id word
#>   <int> <chr>
#> 1 1022 Prince
#> 2 1022 of
#> 3 1022 Winterfell
#> 4 1022 Lord
#> 5 1022 of
#> 6 1022 the
#> # ... with 192 more rows
```

And then we can count that column to find the most common words:

```
titles |>
  mutate(word = str_split(title, " "), .keep = "unused")
  unnest_longer(word) |>
  count(word, sort = TRUE)
#> # A tibble: 77 × 2
#>   word          n
#>   <chr>     <int>
#> 1 of            40
#> 2 the           29
#> 3 Lord           9
#> 4 Hand            6
#> 5 King            5
#> 6 Princess         5
#> # ... with 71 more rows
```

Some of those words are not very interesting so we could create a list of common words to drop. In text analysis these are commonly called stop words.

```
stop_words <- tibble(word = c("of", "the"))

titles |>
  mutate(word = str_split(title, " "), .keep = "unused")
  unnest_longer(word) |>
  anti_join(stop_words) |>
  count(word, sort = TRUE)
#> Joining with `by = join_by(word)`
#> # A tibble: 75 × 2
#>   word          n
#>   <chr>     <int>
#> 1 Lord           9
#> 2 Hand            6
#> 3 King            5
```

```
#> 4 Princess      5  
#> 5 Queen        5  
#> 6 Ser          5  
#> # ... with 69 more rows
```

Breaking up text into individual fragments is a powerful idea that underlies much of text analysis. If this sounds interesting, a good place to learn more is [Text Mining with R](#) by Julia Silge and David Robinson.

25.4.4 Deeply nested

We'll finish off these case studies with a list-column that's very deeply nested and requires repeated rounds of `unnest_wider()` and `unnest_longer()` to unravel: `gmaps_cities`. This is a two column tibble containing five city names and the results of using Google's [geocoding API](#) to determine their location:

```
gmaps_cities  
#> # A tibble: 5 × 2  
#>   city      json  
#>   <chr>     <list>  
#> 1 Houston   <named list [2]>  
#> 2 Washington <named list [2]>  
#> 3 New York  <named list [2]>  
#> 4 Chicago   <named list [2]>  
#> 5 Arlington <named list [2]>
```

`json` is a list-column with internal names, so we start with an `unnest_wider()`:

```
gmaps_cities |>  
  unnest_wider(json)  
#> # A tibble: 5 × 3  
#>   city      results    status
```

```
#>   <chr>      <list>      <chr>
#> 1 Houston    <list [1]> OK
#> 2 Washington <list [2]> OK
#> 3 New York   <list [1]> OK
#> 4 Chicago    <list [1]> OK
#> 5 Arlington  <list [2]> OK
```

This gives us the `status` and the `results`. We'll drop the `status` column since they're all `OK`; in a real analysis, you'd also want to capture all the rows where `status != "OK"` and figure out what went wrong. `results` is an unnamed list, with either one or two elements (we'll see why shortly) so we'll unnest it into rows:

```
gmaps_cities |>
  unnest_wider(json) |>
  select(-status) |>
  unnest_longer(results)
#> # A tibble: 7 × 2
#>   city      results
#>   <chr>     <list>
#> 1 Houston    <named list [5]>
#> 2 Washington <named list [5]>
#> 3 Washington <named list [5]>
#> 4 New York   <named list [5]>
#> 5 Chicago    <named list [5]>
#> 6 Arlington  <named list [5]>
#> # ... with 1 more row
```

Now `results` is a named list, so we'll use `unnest_wider()`:

```
locations <- gmaps_cities |>
  unnest_wider(json) |>
  select(-status) |>
  unnest_longer(results) |>
  unnest_wider(results)
locations
```

```
#> # A tibble: 7 × 6
#>   city      address_components formatted_address geo
#>   <chr>     <list>           <chr>           <li
#> 1 Houston    <list [4]>       Houston, TX, USA <na
#> 2 Washington <list [2]>       Washington, USA  <na
#> 3 Washington <list [4]>       Washington, DC, ... <na
#> 4 New York   <list [3]>       New York, NY, USA <na
#> 5 Chicago    <list [4]>       Chicago, IL, USA <na
#> 6 Arlington  <list [4]>       Arlington, TX, U... <na
#> # ... with 1 more row, and abbreviated variable name `l
```

Now we can see why two cities got two results: Washington matched both Washington state and Washington, DC, and Arlington matched Arlington, Virginia and Arlington, Texas.

There are few different places we could go from here. We might want to determine the exact location of the match, which is stored in the geometry list-column:

```
locations |>
  select(city, formatted_address, geometry) |>
  unnest_wider(geometry)
#> # A tibble: 7 × 6
#>   city      formatted_address bounds      location
#>   <chr>     <chr>           <list>      <list>
#> 1 Houston    Houston, TX, USA <named list> <named li
#> 2 Washington Washington, USA <named list> <named li
#> 3 Washington Washington, DC, ... <named list> <named li
#> 4 New York   New York, NY, USA <named list> <named li
#> 5 Chicago    Chicago, IL, USA <named list> <named li
#> 6 Arlington  Arlington, TX, U... <named list> <named li
#> # ... with 1 more row, and abbreviated variable name `l
```

That gives us new `bounds` (a rectangular region) and `location` (a point). We can unnest `location` to see the latitude (`lat`) and longitude (`lng`):

```
locations |>
  select(city, formatted_address, geometry) |>
  unnest_wider(geometry) |>
  unnest_wider(location)

#> # A tibble: 7 × 7
#>   city      formatted_address bounds          lat    lng
#>   <chr>    <chr>           <list>        <dbl>   <dbl>
#> 1 Houston   Houston, TX, USA <named list> 29.8   -96
#> 2 Washington Washington, USA <named list> 47.8  -122
#> 3 Washington Washington, DC, ... <named list> 38.9  -77
#> 4 New York  New York, NY, USA <named list> 40.7  -74
#> 5 Chicago   Chicago, IL, USA <named list> 41.9  -87
#> 6 Arlington Arlington, TX, U... <named list> 32.7  -97
#> # ... with 1 more row, and abbreviated variable name `l`
```

Extracting the bounds requires a few more steps:

```
locations |>
  select(city, formatted_address, geometry) |>
  unnest_wider(geometry) |>
  # focus on the variables of interest
  select(!location:viewport) |>
  unnest_wider(bounds)

#> # A tibble: 7 × 4
#>   city      formatted_address   northeast      south
#>   <chr>    <chr>           <list>        <list>
#> 1 Houston   Houston, TX, USA <named list [2]> <na...
#> 2 Washington Washington, USA <named list [2]> <na...
#> 3 Washington Washington, DC, USA <named list [2]> <na...
#> 4 New York  New York, NY, USA <named list [2]> <na...
```

```
#> 5 Chicago    Chicago, IL, USA    <named list [2]> <na
#> 6 Arlington  Arlington, TX, USA  <named list [2]> <na
#> # ... with 1 more row
```

We then rename `southwest` and `northeast` (the corners of the rectangle) so we can use `names_sep` to create short but evocative names:

```
locations |>
  select(city, formatted_address, geometry) |>
  unnest_wider(geometry) |>
  select(!location:viewport) |>
  unnest_wider(bounds) |>
  rename(ne = northeast, sw = southwest) |>
  unnest_wider(c(ne, sw), names_sep = "_")
#> # A tibble: 7 × 6
#>   city      formatted_address    ne_lat ne_lng sw_lat
#>   <chr>    <chr>            <dbl>   <dbl>   <dbl>
#> 1 Houston   Houston, TX, USA    30.1   -95.0   29.5
#> 2 Washington Washington, USA   49.0   -117.   45.5
#> 3 Washington Washington, DC, USA 39.0   -76.9   38.8
#> 4 New York  New York, NY, USA   40.9   -73.7   40.5
#> 5 Chicago    Chicago, IL, USA    42.0   -87.5   41.6
#> 6 Arlington  Arlington, TX, USA 32.8   -97.0   32.6
#> # ... with 1 more row
```

Note how we unnest two columns simultaneously by supplying a vector of variable names to `unnest_wider()`.

This is where `hoist()`, mentioned earlier in the chapter, can be useful. Once you've discovered the path to get to the components you're interested in, you can extract them directly using `hoist()`:

```
locations |>
  select(city, formatted_address, geometry) |>
  hoist(
    geometry,
    ne_lat = c("bounds", "northeast", "lat"),
    sw_lat = c("bounds", "southwest", "lat"),
    ne_lng = c("bounds", "northeast", "lng"),
    sw_lng = c("bounds", "southwest", "lng"),
  )
#> # A tibble: 7 × 7
#>   city      formatted_address    ne_lat  sw_lat  ne_lng

#> 6 Arlington Arlington, TX, USA 32.8    32.6   -97.0
#> # ... with 1 more row
```

If these case studies have whetted your appetite for more real-life rectangling, you can see a few more examples in
`vignette("rectangling", package = "tidyverse")`.

25.4.5 Exercises

1. Roughly estimate when `gh_repos` was created. Why can you only roughly estimate the date?
2. The `owner` column of `gh_repo` contains a lot of duplicated information because each owner can have many repos. Can you construct a `owners` data frame that contains one row for each owner? (Hint: does `distinct()` work with list-cols?)

3. Explain the following code line-by-line. Why is it interesting? Why does it work for `got_chars` but might not work in general?

```
tibble(json = got_chars) |>
  unnest_wider(json) |>
  select(id, where(is.list)) |>
  pivot_longer(
    where(is.list),
    names_to = "name",
    values_to = "value"
  ) |>
  unnest_longer(value)
```

4. In `gmaps_cities`, what does `address_components` contain?

Why does the length vary between rows? Unnest it appropriately to figure it out. (Hint: `types` always appears to contain two elements. Does `unnest_wider()` make it easier to work with than `unnest_longer()`?).

25.5 JSON

All of the case studies in the previous section were sourced from wild-caught JSON. JSON is short for **j**avascript **o**bject **n**otation and is the way that most web APIs return data. It's important to understand it because while JSON and R's data types are pretty similar, there isn't a perfect 1-to-1 mapping, so it's good to understand a bit about JSON if things go wrong.

25.5.1 Data types

JSON is a simple format designed to be easily read and written by machines, not humans. It has six key data types. Four of them are scalars:

- The simplest type is a null (`null`) which plays the same role as both `NULL` and `NA` in R. It represents the absence of data.
- A **string** is much like a string in R, but must always use double quotes.
- A **number** is similar to R's numbers: they can use integer (e.g. 123), decimal (e.g. 123.45), or scientific (e.g. 1.23e3) notation. JSON doesn't support `Inf`, `-Inf`, or `NaN`.
- A **boolean** is similar to R's `TRUE` and `FALSE`, but uses lowercase `true` and `false`.

JSON's strings, numbers, and booleans are pretty similar to R's character, numeric, and logical vectors. The main difference is that JSON's scalars can only represent a single value. To represent multiple values you need to use one of the two remaining types: arrays and objects.

Both arrays and objects are similar to lists in R; the difference is whether or not they're named. An **array** is like an unnamed list, and is written with `[]`. For example `[1, 2, 3]` is an array containing 3 numbers, and `[null, 1, "string", false]` is an array that contains a null, a number, a string, and a boolean. An **object** is like a named list, and is written with `{}`. The names (keys in JSON terminology) are strings, so must be surrounded by quotes. For example, `{"x": 1, "y": 2}` is an object that maps `x` to 1 and `y` to 2.

25.5.2 jsonlite

To convert JSON into R data structures, we recommend the `jsonlite` package, by Jeroen Ooms. We'll use only two `jsonlite` functions: `read_json()` and `parse_json()`. In real life, you'll use `read_json()` to read a JSON file from disk. For example, the `repurrsive` package also provides the source for `gh_user` as a JSON file and you can read it with `read_json()`:

```
# A path to a json file inside the package:  
gh_users_json()  
#> [1] "/home/runner/work/_temp/Library/repurrrsive/exta  
  
# Read it with read_json()  
gh_users2 <- read_json(gh_users_json())  
  
# Check it's the same as the data we were using previously  
identical(gh_users, gh_users2)  
#> [1] TRUE
```

In this book, we'll also use `parse_json()`, since it takes a string containing JSON, which makes it good for generating simple examples. To get started, here are three simple JSON datasets, starting with a number, then putting a few numbers in an array, then putting that array in an object:

```
str(parse_json('1'))  
#> int 1  
str(parse_json('[1, 2, 3]))  
#> List of 3  
#> $ : int 1  
#> $ : int 2  
#> $ : int 3  
str(parse_json('>{"x": [1, 2, 3]}'))  
#> List of 1  
#> $ x:List of 3  
#>   ..$ : int 1  
#>   ..$ : int 2  
#>   ..$ : int 3
```

jsonlite has another important function called `fromJSON()`. We don't use it here because it performs automatic simplification (`simplifyVector = TRUE`). This often works well, particularly in simple cases, but we think you're better off doing the rectangling yourself so you know exactly what's happening and can more easily handle the most complicated nested structures.

25.5.3 Starting the rectangling process

In most cases, JSON files contain a single top-level array, because they're designed to provide data about multiple "things", e.g. multiple pages, or multiple records, or multiple results. In this case, you'll start your rectangling with `tibble(json)` so that each element becomes a row:

```
json <- '[{"name": "John", "age": 34}, {"name": "Susan", "age": 27}]'
df <- tibble(json = parse_json(json))
df
#> # A tibble: 2 × 1
#>   json
#>   <list>
#> 1 <named list [2]>
#> 2 <named list [2]>

df |>
  unnest_wider(json)
#> # A tibble: 2 × 2
#>   name    age
#>   <chr> <int>
#> 1 John     34
#> 2 Susan    27
```

In rarer cases, the JSON file consists of a single top-level JSON object, representing one “thing”. In this case, you’ll need to kick off the rectangling process by wrapping it in a list, before you put it in a tibble.

```
json <- '{
  "status": "OK",
  "results": [
    {"name": "John", "age": 34},
    {"name": "Susan", "age": 27}
  ]
}

df <- tibble(json = list(parse_json(json)))
df
#> # A tibble: 1 × 1
#>   json
#>   <list>
#> 1 <named list [2]>

df |>
  unnest_wider(json) |>
  unnest_longer(results) |>
  unnest_wider(results)
#> # A tibble: 2 × 3
#>   status name    age
#>   <chr>  <chr> <int>
#> 1 OK      John     34
#> 2 OK      Susan    27
```

Alternatively, you can reach inside the parsed JSON and start with the bit that you actually care about:

```
df <- tibble(results = parse_json(json)$results)
df |>
  unnest_wider(results)
#> # A tibble: 2 × 2
```

```
#>   name    age
#>   <chr> <int>
#> 1 John     34
#> 2 Susan    27
```

25.5.4 Translation challenges

Since JSON doesn't have any way to represent dates or date-times, they're often stored as ISO8601 date times in strings, and you'll need to use `readr::parse_date()` or `readr::parse_datetime()` to turn them into the correct data structure. Similarly, JSON's rules for representing floating point numbers in JSON are a little imprecise, so you'll also sometimes find numbers stored in strings. Apply `readr::parse_double()` as needed to the get correct variable type.

25.5.5 Exercises

1. Rectangle the `df_col` and `df_row` below. They represent the two ways of encoding a data frame in JSON.

```
json_col <- parse_json('
{
  "x": ["a", "x", "z"],
  "y": [10, null, 3]
}
')
json_row <- parse_json([
  {
    "x": "a", "y": 10},
    {"x": "x", "y": null},
    {"x": "z", "y": 3}
]
')
```

```
df_col <- tibble(json = list(json_col))  
df_row <- tibble(json = json_row)
```

25.6 Summary

In this chapter, you learned what lists are, how you can generate them from JSON files, and how turn them into rectangular data frames.

Surprisingly we only need two new functions: `unnest_longer()` to put list elements into rows and `unnest_wider()` to put list elements into columns. It doesn't matter how deeply nested the list-column is, all you need to do is repeatedly call these two functions.

JSON is the most common data format returned by web APIs. What happens if the website doesn't have an API, but you can see data you want on the website? That's the topic of the next chapter: web scraping, extracting data from HTML webpages.

1. This is an RStudio feature. 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

This vignette introduces you to the basics of web scraping with [rvest](#). Web scraping is a very useful tool for extracting data from web pages. Some websites will offer an API, a set of structured HTTP requests that return data as JSON, which you handle using the techniques from [Chapter 25](#). Where possible, you should use the API, because typically it will give you more reliable data. Unfortunately, however, programming with web APIs is out of scope for this book. Instead, we are teaching scraping, a technique that works whether or not a site provides an API.

In this chapter, we'll first discuss the ethics and legalities of scraping before we dive into the basics of HTML. You'll then learn the basics of CSS selectors to locate specific elements on the page, and how to use rvest functions to get data from text and attributes out of HTML and into R. We'll then discuss some techniques to figure out what CSS selector you need for the page you're scraping, before finishing up with a couple of case studies, and a brief discussion of dynamic websites.

26.0.1 Prerequisites

In this chapter, we'll focus on tools provided by rvest. rvest is a member of the tidyverse, but is not a core member so you'll need to load it explicitly. We'll also load the full tidyverse since we'll find it generally useful working with the data we've scraped.

```
library(tidyverse)
```

```
library(rvest)
```

26.1 Scraping ethics and legalities

Before we get started discussing the code you'll need to perform web scraping, we need to talk about whether it's legal and ethical for you to do so. Overall, the situation is complicated with regards to both of these.

Legalities depend a lot on where you live. However, as a general principle, if the data is public, non-personal, and factual, you're likely to be ok¹. These three factors are important because they're connected to the site's terms and conditions, personally identifiable information, and copyright, as we'll discuss below.

If the data isn't public, non-personal, or factual or you're scraping the data specifically to make money with it, you'll need to talk to a lawyer. In any case, you should be respectful of the resources of the server hosting the pages you are scraping. Most importantly, this means that if you're scraping many pages, you should make sure to wait a little between each request. One easy way to do so is to use the [**polite**](#) package by Dmytro Perepolkin. It will automatically pause between requests and cache the results so you never ask for the same page twice.

26.1.1 Terms of service

If you look closely, you'll find many websites include a "terms and conditions" or "terms of service" link somewhere on the page, and if you read that page closely you'll often discover that the site specifically prohibits web scraping. These pages tend to be a legal land grab where

companies make very broad claims. It's polite to respect these terms of service where possible, but take any claims with a grain of salt.

US courts² have generally found that simply putting the terms of service in the footer of the website isn't sufficient for you to be bound by them. Generally, to be bound to the terms of service, you must have taken some explicit action like creating an account or checking a box. This is why whether or not the data is **public** is important; if you don't need an account to access them, it is unlikely that you are bound to the terms of service. Note, however, the situation is rather different in Europe where courts have found that terms of service are enforceable even if you don't explicitly agree to them.

26.1.2 Personally identifiable information

Even if the data is public, you should be extremely careful about scraping personally identifiable information like names, email addresses, phone numbers, dates of birth, etc. Europe has particularly strict laws about the collection of storage of such data (GDPR), and regardless of where you live you're likely to be entering an ethical quagmire. For example, in 2016, a group of researchers scraped public profile information (e.g., usernames, age, gender, location, etc.) about 70,000 people on the dating site OkCupid and they publicly released these data without any attempts for anonymization. While the researchers felt that there was nothing wrong with this since the data were already public, this work was widely condemned due to ethics concerns around identifiability of users whose information was released in the dataset. If your work involves scraping personally identifiable information, we strongly recommend reading about the OkCupid study as well as similar studies with questionable research ethics involving the acquisition and release of personally identifiable information.³

26.1.3 Copyright

Finally, you also need to worry about copyright law. Copyright law is complicated, but it's worth taking a look at the [US law](#) which describes exactly what's protected: “[...] original works of authorship fixed in any tangible medium of expression, [...]”. It then goes on to describe specific categories that it applies like literary works, musical works, motions pictures and more. Notably absent from copyright protection are data. This means that as long as you limit your scraping to facts, copyright protection does not apply. (But note that Europe has a separate “[sui generis](#)” right that protects databases.)

As a brief example, in the US, lists of ingredients and instructions are not copyrightable, so copyright can not be used to protect a recipe. But if that list of recipes is accompanied by substantial novel literary content, that is copyrightable. This is why when you're looking for a recipe on the internet there's always so much content beforehand.

If you do need to scrape original content (like text or images), you may still be protected under the [doctrine of fair use](#). Fair use is not a hard and fast rule, but weighs up a number of factors. It's more likely to apply if you are collecting the data for research or non-commercial purposes and if you limit what you scrape to just what you need.

26.2 HTML basics

To scrape webpages, you need to first understand a little bit about **HTML**, the language that describes web pages. HTML stands for **HyperText Markup Language** and looks something like this:

```
<html>
<head>
  <title>Page title</title>
</head>
<body>
```

```
<h1 id='first'>A heading</h1>
<p>Some text &amp;lt; b &gt;some bold text.</b></p>
<img src='myimg.png' width='100' height='100'>
</body>
```

HTML has a hierarchical structure formed by **elements** which consist of a start tag (e.g. `<tag>`), optional **attributes** (`id='first'`), an end tag⁴ (like `</tag>`), and **contents** (everything in between the start and end tag).

Since `<` and `>` are used for start and end tags, you can't write them directly. Instead you have to use the HTML **escapes** `>` (greater than) and `<` (less than). And since those escapes use `&`, if you want a literal ampersand you have to escape it as `&`. There are a wide range of possible HTML escapes but you don't need to worry about them too much because rvest automatically handles them for you.

Web scraping is possible because most pages that contain data that you want to scrape generally have a consistent structure.

26.2.1 Elements

All up, there are over 100 HTML elements. Some of the most important are:

- Every HTML page must be in an `<html>` element, and it must have two children: `<head>`, which contains document metadata like the page title, and `<body>`, which contains the content you see in the browser.
- Block tags like `<h1>` (heading 1), `<section>` (section), `<p>` (paragraph), and `` (ordered list) form the overall structure of the page.

- Inline tags like `` (bold), `<i>` (italics), and `<a>` (link) format text inside block tags.

If you encounter a tag that you've never seen before, you can find out what it does with a little googling. Another good place to start are the [MDN Web Docs](#) which describe just about every aspect of web programming.

Most elements can have content in between their start and end tags. This content can either be text or more elements. For example, the following HTML contains paragraph of text, with one word in bold.

```
<p>
  Hi! My <b>name</b> is Hadley.
</p>
```

The **children** of a node refers only to elements, so the `<p>` element above has one child, the `` element. The `` element has no children, but it does have contents (the text “name”).

26.2.2 Attributes

Tags can have named **attributes** which look like `name1='value1'` `name2='value2'`. Two of the most important attributes are `id` and `class`, which are used in conjunction with CSS (Cascading Style Sheets) to control the visual appearance of the page. These are often useful when scraping data off a page. Attributes are also used to record the destination of links (the `href` attribute of `<a>` elements) and the source of images (the `src` attribute of the `` element).

26.3 Extracting data

To get started scraping, you'll need the URL of the page you want to scrape, which you can usually copy from your web browser. You'll then need to read the HTML for that page into R with `read_html()`. This returns a `xml_document`⁵ object which you'll then manipulate using rvest functions:

```
html <- read_html("http://rvest.tidyverse.org/")
html
#> {html_document}
#> <html lang="en">
#> [1] <head>\n<meta http-equiv="Content-Type" content="
#> [2] <body>\n      <a href="#container" class="visually-
```

rvest also includes a function that lets you write HTML inline. We'll use this a bunch in this chapter as we teach how the various rvest functions work with simple examples.

```
html <- minimal_html("
<p>This is a paragraph<p>
<ul>
  <li>This is a bulleted list</li>
</ul>
")
html
#> {html_document}
#> <html>
#> [1] <head>\n<meta http-equiv="Content-Type" content="
#> [2] <body>\n<p>This is a paragraph</p>\n<p>\n  </p>\n</body>
```

Now that you have the HTML in R, it's time to extract the data of interest. You'll first learn about the CSS selectors that allow you to identify the

elements of interest and the `rvest` functions that you can use to extract data from them. Then we'll briefly cover HTML tables, which have some special tools.

26.3.1 Find elements

CSS is short for cascading style sheets, and is a tool for defining the visual styling of HTML documents. CSS includes a miniature language for selecting elements on a page called **CSS selectors**. CSS selectors define patterns for locating HTML elements, and are useful for scraping because they provide a concise way of describing which elements you want to extract.

We'll come back to CSS selectors in more detail in [Section 26.4](#), but luckily you can get a long way with just three:

- `p` selects all `<p>` elements.
- `.title` selects all elements with `class` “`title`”.
- `#title` selects the element with the `id` attribute that equals “`title`”. `Id` attributes must be unique within a document, so this will only ever select a single element.

Lets try out these selectors with a simple example:

```
html <- minimal_html("  
  <h1>This is a heading</h1>  
  <p id='first'>This is a paragraph</p>  
  <p class='important'>This is an important paragraph</p>  
)
```

Use `html_elements()` to find all elements that match the selector:

```
html |> html_elements("p")
#> {xml_nodeset (2)}
#> [1] <p id="first">This is a paragraph</p>
#> [2] <p class="important">This is an important paragra
html |> html_elements(".important")
#> {xml_nodeset (1)}
#> [1] <p class="important">This is an important paragra
html |> html_elements("#first")
#> {xml_nodeset (1)}
#> [1] <p id="first">This is a paragraph</p>
```

Another important function is `html_element()` which always the number of outputs as inputs. If you apply it to a whole document it'll give you the first match:

```
html |> html_element("p")
#> {html_node}
#> <p id="first">
```

There's an important difference between `html_element()` and `html_elements()` when you use a selector that doesn't match any elements. `html_elements()` returns a vector of length 0, where `html_element()` returns a missing value. This will be important shortly.

```
html |> html_elements("b")
#> {xml_nodeset (0)}
html |> html_element("b")
#> {xml_missing}
#> <NA>
```

26.3.2 Nesting selections

In most cases, you'll use `html_elements()` and `html_element()` together, typically using `html_elements()` to identify elements that will become observations then using `html_element()` to find elements that will become variables. Let's see this in action using a simple example. Here we have an unordered list (``) where each list item (``) contains some information about four characters from StarWars:

```
html <- minimal_html("
<ul>
  <li><b>C-3P0</b> is a <i>droid</i> that weighs <span
  <li><b>R2-D2</b> is a <i>droid</i> that weighs <span
  <li><b>Yoda</b> weighs <span class='weight'>66 kg</s
  <li><b>R4-P17</b> is a <i>droid</i></li>
</ul>
")
```

We can use `html_elements()` to make a vector where each element corresponds to a different character:

```
characters <- html |> html_elements("li")
characters
#> {xml_nodeSet (4)}
#> [1] <li>\n<b>C-3P0</b> is a <i>droid</i> that weighs
#> [2] <li>\n<b>R2-D2</b> is a <i>droid</i> that weighs
#> [3] <li>\n<b>Yoda</b> weighs <span class="weight">66
#> [4] <li>\n<b>R4-P17</b> is a <i>droid</i>\n</li>
```

To extract the name of each character, we use `html_element()`, because when applied to the output of `html_elements()` its guaranteed to return one response per element:

```
characters |> html_element("b")
#> {xml_nodeSet (4)}
#> [1] <b>C-3PO</b>
#> [2] <b>R2-D2</b>
#> [3] <b>Yoda</b>
#> [4] <b>R4-P17</b>
```

The distinction between `html_element()` and `html_elements()` isn't important for name, but it is important for weight. We want to try and get the weight for each character

```
characters |> html_element(".weight")
#> {xml_nodeSet (4)}
#> [1] <span class="weight">167 kg</span>
#> [2] <span class="weight">96 kg</span>
#> [3] <span class="weight">66 kg</span>
#> [4] <NA>
```

If we instead used `html_elements()`, we lose the connection between names and weights:

```
characters |> html_elements(".weight")
#> {xml_nodeSet (3)}
#> [1] <span class="weight">167 kg</span>
#> [2] <span class="weight">96 kg</span>
#> [3] <span class="weight">66 kg</span>
```

Now that you've selected the elements of interest, you'll need to extract the data, either from the text contents or some attributes.

26.3.3 Text and attributes

`html_text2()`⁶ extracts the plain text contents of an HTML element:

```
html <- minimal_html("  
  <ol>  
    <li>apple & pear</li>  
    <li>banana</li>  
    <li>pineapple</li>  
  </ol>  
")  
html |>  
  html_element("ol") |>  
  html_elements("li") |>  
  html_text2()  
#> [1] "apple & pear" "banana"       "pineapple"
```

Note that the escaped ampersand is automatically converted to `&`; you'll only ever see HTML escapes in the source HTML, not in the data returned by rvest.

`html_attr()` extracts data from attributes:

```
html <- minimal_html("  <p><a href='https://en.wikipedia.org/wiki/Cat'>cats</a>  
  <p><a href='https://en.wikipedia.org/wiki/Dog'>dogs</a>  
")  
  
html |>  
  html_elements("p") |>  
  html_element("a") |>  
  html_attr("href")  
#> [1] "https://en.wikipedia.org/wiki/Cat" "https://en.w
```

`html_attr()` always returns a string, so if you're extracting numbers or dates, you'll need to do some post-processing.

26.3.4 Tables

If you're lucky, your data will be already stored in an HTML table, and it'll be a matter of just reading it from that table. It's usually straightforward to recognize a table in your browser: it'll have a rectangular structure of rows and columns, and you can copy and paste it into a tool like Excel.

HTML tables are built up from four main elements: `<table>`, `<tr>` (table row), `<th>` (table heading), and `<td>` (table data). Here's a simple HTML table with two columns and three rows:

```
html <- minimal_html("  
  <table class='mytable'>  
    <tr>  
      <th>x</th>  
      <th>y</th>  
    </tr>  
    <tr>  
      <td>1.5</td>  
      <td>2.7</td>  
    </tr>  
    <tr>  
      <td>4.9</td>  
      <td>1.3</td>  
    </tr>  
    <tr>  
      <td>7.2</td>  
      <td>8.1</td>  
    </tr>  
  </table>  
")
```

rvest provides a function that knows how to read this sort of data: `html_table()`. It returns a list containing one tibble for each table found on the page. Use `html_element()` to identify the table you want to extract:

```
html |>  
  html_element(".mytable") |>  
  html_table()  
#> # A tibble: 3 × 2  
#>       x     y  
#>   <dbl> <dbl>  
#> 1    1.5   2.7  
#> 2    4.9   1.3  
#> 3    7.2   8.1
```

Note that `x` and `y` have automatically been converted to numbers. This automatic conversion doesn't always work, so in more complex scenarios you may want to turn it off with `convert = FALSE` and then do your own conversion.

26.4 Finding the right selectors

Figuring out the selector you need for your data is typically the hardest part of the problem. You'll often need to do some experimenting to find a selector that is both specific (i.e. it doesn't select things you don't care about) and sensitive (i.e. it does select everything you care about). Lots of trial and error is a normal part of the process! There are two main tools that are available to help you with this process: SelectorGadget and your browser's developer tools.

[SelectorGadget](#) is a javascript bookmarklet that automatically generates CSS selectors based on the positive and negative examples that you provide. It doesn't always work, but when it does, it's magic! You can

learn how to install and use SelectorGadget either by reading <https://rvest.tidyverse.org/articles/selectorgadget.html> or watching Mine's video at <https://www.youtube.com/watch?v=PetWV5g1Xsc>.

Every modern browser comes with some toolkit for developers, but we recommend Chrome, even if it isn't your regular browser: its web developer tools are some of the best and they're immediately available. Right click on an element on the page and click `Inspect`. This will open an expandable view of the complete HTML page, centered on the element that you just clicked. You can use this to explore the page and get a sense of what selectors might work. Pay particular attention to the class and id attributes, since these are often used to form the visual structure of the page, and hence make for good tools to extract the data that you're looking for.

Inside the Elements view, you can also right click on an element and choose `Copy as Selector` to generate a selector that will uniquely identify the element of interest.

If either SelectorGadget or Chrome DevTools have generated a CSS selector that you don't understand, try [Selectors Explained](#) which translates CSS selectors into plain English. If you find yourself doing this a lot, you might want to learn more about CSS selectors generally. We recommend starting with the fun [CSS dinner](#) tutorial and then referring to the [MDN web docs](#).

26.5 Putting it all together

Lets put this all together to scrape some websites. There's some risk that these examples may no longer work when you run them — that's the fundamental challenge of web scraping; if the structure of the site changes, then you'll have to change your scraping code.

26.5.1 StarWars

rvest includes a very simple example in `vignette("starwars")`. This is simple page with minimal HTML so it's a good place to start. I'd encourage you to navigate to that page now and use "Inspect Element" to inspect one of the headings that's the title of a Star Wars movie. Use the keyboard or mouse to explore the hierarchy of the HTML and see if you can get a sense of the shared structure used by each movie.

You should be able to see that each movie has a shared structure that looks like this:

```
<section>
  <h2 data-id="1">The Phantom Menace</h2>
  <p>Released: 1999-05-19</p>
  <p>Director: <span class="director">George Lucas</span>

  <div class="crawl">
    <p>...</p>
    <p>...</p>
    <p>...</p>
  </div>
</section>
```

Our goal is to turn this data into a 7 row data frame with variables `title`, `year`, `director`, and `intro`. We'll start by reading the HTML and extracting all the `<section>` elements:

```
url <- "https://rvest.tidyverse.org/articles/starwars.html"
html <- read_html(url)

section <- html |> html_elements("section")
```

```
section
#> {xml_nodeset (7)}
#> [1] <section><h2 data-id="1">\nThe Phantom Menace\n</h2>
#> [2] <section><h2 data-id="2">\nAttack of the Clones\n</h2>
#> [3] <section><h2 data-id="3">\nRevenge of the Sith\n</h2>
#> [4] <section><h2 data-id="4">\nA New Hope\n</h2>\n<p>
#> [5] <section><h2 data-id="5">\nThe Empire Strikes Back\n</h2>
#> [6] <section><h2 data-id="6">\nReturn of the Jedi\n</h2>
#> [7] <section><h2 data-id="7">\nThe Force Awakens\n</h2>
```

The retrieves seven nodes matching the seven movies found on that page, suggesting that using `section` as a selector is good. Extracting the individual elements is straightforward since the data is always found in the text. It's just a matter of finding the right selector:

```
section |> html_element("h2") |> html_text2()
#> [1] "The Phantom Menace"      "Attack of the Clones"
#> [3] "Revenge of the Sith"     "A New Hope"
#> [5] "The Empire Strikes Back" "Return of the Jedi"
#> [7] "The Force Awakens"

section |> html_element(".director") |> html_text2()
#> [1] "George Lucas"          "George Lucas"          "George Lucas"
#> [4] "George Lucas"          "Irvin Kershner"       "Richard Marquand"
#> [7] "J. J. Abrams"
```

Once we've done that for each component, we can wrap all the results up into a tibble:

```
tibble(
  title = section |> html_element("h2") |> html_text2(),
  released = section |>
    html_element("p") |>
```

```
html_text2() |>
str_remove("Released: ") |>
parse_date(),
director = section |> html_element(".director") |> html_text
intro = section |> html_element(".crawl") |> html_text
)
#> # A tibble: 7 × 4
#>   title           released    director
#>   <chr>          <date>      <chr>
#> 1 The Phantom Menace 1999-05-19 George Lucas
#> 2 Attack of the Clones 2002-05-16 George Lucas
#> 3 Revenge of the Sith 2005-05-19 George Lucas
#> 4 A New Hope       1977-05-25 George Lucas
#> 5 The Empire Strikes Back 1980-05-17 Irvin Kershner
#> 6 Return of the Jedi 1983-05-25 Richard Marquand
#> # ... with 1 more row
```

We did a little more processing of `released` to get a variable that will be easy to use later in our analysis.

26.5.2 IMDB top films

For our next task we'll tackle something a little trickier, extracting the top 250 movies from the internet movie database (IMDb). At the time we wrote this chapter, the page looked like [Figure 26.1](#).

```
knitr::include_graphics("screenshots/scraping-imdb.png"),
```

IMDb Charts

IMDb Top 250 Movies

IMDb Top 250 as rated by regular IMDb voters.

SHARE

Showing 250 Titles

Sort by: Ranking  

Rank & Title	IMDb Rating	Your Rating	
1. The Shawshank Redemption (1994)	 9.2		
2. The Godfather (1972)	 9.2		
3. The Dark Knight (2008)	 9.0		
4. The Godfather: Part II (1974)	 9.0		
5. 12 Angry Men (1957)	 9.0		
6. Schindler's List (1993)	 8.9		
7. The Lord of the Rings: The Return of the King (2003)	 8.9		
8. Pulp Fiction (1994)	 8.8		

Figure 26.1: Screenshot of the IMDb top movies web page taken on 2022-12-05.

This data has a clear tabular structure so it's worth starting with `html_table()`:

```
url <- "https://www.imdb.com/chart/top"
html <- read_html(url)

table <- html |>
  html_element("table") |>
```

```
html_table()
table
#> # A tibble: 250 × 5
#>   ``     `Rank & Title` 
#>   <lgl> <chr>
#> 1 NA    "1.\n      The Shawshank Redemption\n"
#> 2 NA    "2.\n      The Godfather\n      (1972)" 
#> 3 NA    "3.\n      The Dark Knight\n      (2008)" 
#> 4 NA    "4.\n      The Godfather: Part II\n      (1973)" 
#> 5 NA    "5.\n      12 Angry Men\n      (1957)" 
#> 6 NA    "6.\n      Schindler's List\n      (1993)" 
#> # ... with 244 more rows, and abbreviated variable name
#> #   `Your Rating`
```

This includes a few empty columns, but overall does a good job of capturing the information from the table. However, we need to do some more processing to make it easier to use. First, we'll rename the columns to be easier to work with, and remove the extraneous whitespace in rank and title. We will do this with `select()` (instead of `rename()`) to do the renaming and selecting of just these two columns in one step. Then, we'll apply `separate_wider_regex()` (from [Section 17.3.4](#)) to pull out the title, year, and rank into their own variables.

```
ratings <- table |>
  select(
    rank_title_year = `Rank & Title`,
    rating = `IMDb Rating`
  ) |>
  mutate(
    rank_title_year = str_squish(rank_title_year)
  ) |>
  separate_wider_regex(
    rank_title_year,
```

```
patterns = c(
  rank = "\\d+", "\\.",
  title = ".+", "\\(",
  year = "\\d+", "\\)"
)
)
ratings
#> # A tibble: 250 × 4
#>   rank  title           year  rating
#>   <chr> <chr>          <chr>  <dbl>
#> 1 1     The Shawshank Redemption 1994    9.2
#> 2 2     The Godfather          1972    9.2
#> 3 3     The Dark Knight       2008     9
#> 4 4     The Godfather: Part II 1974     9
#> 5 5     12 Angry Men         1957     9
#> 6 6     Schindler's List      1993    8.9
#> # ... with 244 more rows
```

Even in this case where most of the data comes from table cells, it's still worth looking at the raw HTML. If you do so, you'll discover that we can add a little extra data by using one of the attributes. This is one of the reasons it's worth spending a little time spelunking the source of the page; you might find extra data, or might find a parsing route that's slightly easier.

```
html |>
  html_elements("td strong") |>
  head() |>
  html_attr("title")
#> [1] "9.2 based on 2,687,778 user ratings"
#> [2] "9.2 based on 1,864,037 user ratings"
#> [3] "9.0 based on 2,661,139 user ratings"
#> [4] "9.0 based on 1,275,253 user ratings"
#> [5] "9.0 based on 793,945 user ratings"
#> [6] "8.9 based on 1,359,458 user ratings"
```

We can combine this with the tabular data and again apply `separate_wider_regex()` to extract out the bit of data we care about:

```
ratings |>
  mutate(
    rating_n = html |> html_elements("td strong") |> htm
  ) |>
  separate_wider_regex(
    rating_n,
    patterns = c(
      "[0-9.]+ based on ",
      number = "[0-9,]+",
      " user ratings"
    )
  ) |>
  mutate(
    number = parse_number(number)
  )
#> # A tibble: 250 × 5
#>   rank   title           year  rating  number
#>   <chr>  <chr>          <chr>  <dbl>   <dbl>
#> 1 1     The Shawshank Redemption 1994    9.2  2687778
#> 2 2     The Godfather        1972    9.2  1864037
#> 3 3     The Dark Knight      2008     9  2661139
#> 4 4     The Godfather: Part II 1974     9  1275253
#> 5 5     12 Angry Men         1957     9  793945
#> 6 6     Schindler's List      1993    8.9  1359458
#> # ... with 244 more rows
```

26.6 Dynamic sites

From time-to-time, you'll hit a site where `html_elements()` and friends don't return anything like what you see in the browser. In many

cases, that's because you're trying to scrape a website that dynamically generates the content of the page with javascript. This doesn't currently work with rvest, because rvest downloads the raw HTML and doesn't run any javascript.

It's still possible to scrape these types of sites, but rvest needs to use a more expensive process: fully simulating the web browser including running all javascript. This functionality is not available at the time of writing, but it's something we're actively working on and should be available by the time you read this. It uses the [chromote package](#) which actually runs the Chrome browser in the background, and gives you additional tools to interact with the site, like a human typing text and clicking buttons. Check out the rvest website for more details.

26.7 Summary

In this chapter, you've learned about the why, the why not, and the how of scraping data from web pages. First, you've learned about the basics of HTML and using CSS selectors to refer to specific elements, then you've learned about using the rvest package to get data out of HTML into R. We then demonstrated web scraping with two case studies: a simpler scenario on scraping data on StarWars films from the rvest package website and a more complex scenario on scraping the top 250 films from IMDB.

Technical details of scraping data off the web can be complex, particularly when dealing with sites, however legal and ethical considerations can be even more complex. It's important for you to educate yourself about both of these before setting out to scrape data.

This brings us to the end of the wrangling part of the book where you've learned techniques to get data from where it lives (spreadsheets, databases, JSON files, and web sites) into a tidy form in R. Now it's time

to turn our sights to a new topic: making the most of R as a programming language.

1. Obviously we're not lawyers, and this is not legal advice. But this is the best summary we can give having read a bunch about this topic.
2. e.g. https://en.wikipedia.org/wiki/HiQ_Labs_v._LinkedIn
3. One example of an article on the OkCupid study was published by the <https://www.wired.com/2016/05/okcupid-study-reveals-perils-big-data-science>.
4. A number of tags (including `<p>` and ``) don't require end tags, but we think it's best to include them because it makes seeing the structure of the HTML a little easier.
5. This class comes from the `xml2` package. `xml2` is a low-level package that `rvest` builds on top of.
6. `rvest` also provides `html_text()` but you should almost always use `html_text2()` since it does a better job of converting nested HTML to text.

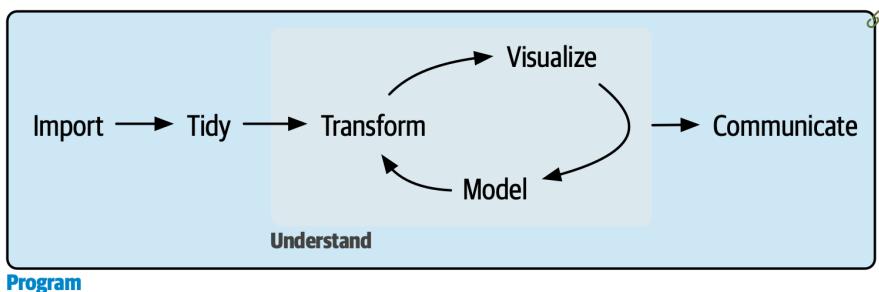

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

Program

>

In this part of the book, you'll improve your programming skills. Programming is a cross-cutting skill needed for all data science work: you must use a computer to do data science; you cannot do it in your head, or with pencil and paper.

Program

Figure 1: Programming is the water in which all other components of the data science process swims.

Programming produces code, and code is a tool of communication. Obviously code tells the computer what you want it to do. But it also communicates meaning to other humans. Thinking about code as a vehicle for communication is important because every project you do is fundamentally collaborative. Even if you're not working with other people, you'll definitely be working with future-you! Writing clear code is important so that others (like future-you) can understand why you tackled an analysis in the way you did. That means getting better at programming also involves getting better at communicating. Over time, you want your code to become not just easier to write, but easier for others to read.

Writing code is similar in many ways to writing prose. One parallel which we find particularly useful is that in both cases rewriting is the key to

clarity. The first expression of your ideas is unlikely to be particularly clear, and you may need to rewrite multiple times. After solving a data analysis challenge, it's often worth looking at your code and thinking about whether or not it's obvious what you've done. If you spend a little time rewriting your code while the ideas are fresh, you can save a lot of time later trying to recreate what your code did. But this doesn't mean you should rewrite every function: you need to balance what you need to achieve now with saving time in the long run. (But the more you rewrite your functions the more likely your first attempt will be clear.)

In the following three chapters, you'll learn skills to improve your programming skills:

1. Copy-and-paste is a powerful tool, but you should avoid doing it more than twice. Repeating yourself in code is dangerous because it can easily lead to errors and inconsistencies. Instead, in [Chapter 27](#), you'll learn how to write **functions** which let you extract out repeated code so that it can be easily reused.
2. Functions extract out repeated code, but you often need to repeat the same actions on different inputs. You need tools for **iteration** that let you do similar things again and again. These tools include for loops and functional programming, which you'll learn about in [Chapter 28](#).
3. As you read more code written by others, you'll see more code that doesn't use the tidyverse. In [Chapter 29](#), you'll learn some of the most important base R functions that you'll see in the wild. These functions tend to be designed to use individual vectors, rather than data frames, often making them a good fit for your programming needs.

Learning more

The goal of these chapters is to teach you the minimum about programming that you need to practice data science. Once you have mastered the material in this book, we strongly believe you should continue to invest in your programming skills. Learning more about programming is a long-term investment: it won't pay off immediately, but in the long term it will allow you to solve new problems more quickly, and let you reuse your insights from previous problems in new scenarios.

To learn more you need to study R as a programming language, not just an interactive environment for data science. We have written two books that will help you do so:

- *[Hands on Programming with R](#)*, by Garrett Grolemund. This is an introduction to R as a programming language and is a great place to start if R is your first programming language. It covers similar material to these chapters, but with a different style and different motivation examples (based in the casino). It's a useful complement if you find that these four chapters go by too quickly.
- *[Advanced R](#)* by Hadley Wickham. This dives into the details of R the programming language. This is a great place to start if you have existing programming experience. It's also a great next step once you've internalized the ideas in these chapters.

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

27.1 Introduction

One of the best ways to improve your reach as a data scientist is to write functions. Functions allow you to automate common tasks in a more powerful and general way than copy-and-pasting. Writing a function has three big advantages over using copy-and-paste:

1. You can give a function an evocative name that makes your code easier to understand.
2. As requirements change, you only need to update code in one place, instead of many.
3. You eliminate the chance of making incidental mistakes when you copy and paste (i.e. updating a variable name in one place, but not in another).

A good rule of thumb is to consider writing a function whenever you've copied and pasted a block of code more than twice (i.e. you now have three copies of the same code). In this chapter, you'll learn about three useful types of functions:

- Vector functions take one or more vectors as input and return a vector as output.

- Data frame functions take a data frame as input and return a data frame as output.
- Plot functions that take a data frame as input and return a plot as output.

Each of these sections include many examples to help you generalize the patterns that you see. These examples wouldn't be possible without the help of folks of twitter, and we encourage follow the links in the comment to see original inspirations. You might also want to read the original motivating tweets for [general functions](#) and [plotting functions](#) to see even more functions.

27.1.1 Prerequisites

We'll wrap up a variety of functions from around the tidyverse. We'll also use nycflights13 as a source of familiar data to use our functions with.

```
library(tidyverse)
library(nycflights13)
```

27.2 Vector functions

We'll begin with vector functions: functions that take one or more vectors and return a vector result. For example, take a look at this code. What does it do?

```
df <- tibble(
  a = rnorm(5),
  b = rnorm(5),
  c = rnorm(5),
  d = rnorm(5),
)
```

```

df |> mutate(
  a = (a - min(a, na.rm = TRUE)) / 
    (max(a, na.rm = TRUE) - min(a, na.rm = TRUE)),
  b = (b - min(b, na.rm = TRUE)) / 
    (max(b, na.rm = TRUE) - min(b, na.rm = TRUE)),
  c = (c - min(c, na.rm = TRUE)) / 
    (max(c, na.rm = TRUE) - min(c, na.rm = TRUE)),
  d = (d - min(d, na.rm = TRUE)) / 
    (max(d, na.rm = TRUE) - min(d, na.rm = TRUE)),
)
#> # A tibble: 5 × 4
#>   a     b     c     d
#>   <dbl> <dbl> <dbl> <dbl>
#> 1 0.339  2.59  0.291  0
#> 2 0.880  0      0.611  0.557
#> 3 0       1.37  1      0.752
#> 4 0.795  1.37  0      1
#> 5 1       1.34  0.580  0.394

```

You might be able to puzzle out that this rescales each column to have a range from 0 to 1. But did you spot the mistake? When Hadley wrote this code he made an error when copying-and-pasting and forgot to change an `a` to a `b`. Preventing this type of mistake of is one very good reason to learn how to write functions.

27.2.1 Writing a function

To write a function you need to first analyse your repeated code to figure what parts are constant and what parts vary. If we take the code above and pull it outside of `mutate()`, it's a little easier to see the pattern because each repetition is now one line:

```
(a - min(a, na.rm = TRUE)) / (max(a, na.rm = TRUE) - min(a, na.rm = TRUE))
(b - min(b, na.rm = TRUE)) / (max(b, na.rm = TRUE) - min(b, na.rm = TRUE))
```

```
(c - min(c, na.rm = TRUE)) / (max(c, na.rm = TRUE) - mi  
(d - min(d, na.rm = TRUE)) / (max(d, na.rm = TRUE) - mi
```

To make this a bit clearer we can replace the bit that varies with █:

```
(█ - min(█, na.rm = TRUE)) / (max(█, na.rm = TRUE) - mi
```

To turn this into a function you need three things:

1. A **name**. Here we'll use `rescale01` because this function rescales a vector to lie between 0 and 1.
2. The **arguments**. The arguments are things that vary across calls and our analysis above tells us that we have just one. We'll call it `x` because this is the conventional name for a numeric vector.
3. The **body**. The body is the code that's repeated across all the calls.

Then you create a function by following the template:

```
name <- function(arguments) {  
  body  
}
```

For this case that leads to:

```
rescale01 <- function(x) {  
  (x - min(x, na.rm = TRUE)) / (max(x, na.rm = TRUE) - mi  
}
```

At this point you might test with a few simple inputs to make sure you've captured the logic correctly:

```
rescale01(c(-10, 0, 10))  
#> [1] 0.0 0.5 1.0  
rescale01(c(1, 2, 3, NA, 5))  
#> [1] 0.00 0.25 0.50 NA 1.00
```

Then you can rewrite the call to `mutate()` as:

```
df |> mutate(  
  a = rescale01(a),  
  b = rescale01(b),  
  c = rescale01(c),  
  d = rescale01(d),  
)  
#> # A tibble: 5 × 4  
#>   a      b      c      d  
#>   <dbl> <dbl> <dbl> <dbl>  
#> 1 0.339  1      0.291  0  
#> 2 0.880  0      0.611  0.557  
#> 3 0       0.530  1      0.752  
#> 4 0.795  0.531  0      1  
#> 5 1       0.518  0.580  0.394
```

(In [Chapter 28](#), you'll learn how to use `across()` to reduce the duplication even further so all you need is `df |> mutate(across(a:d, rescale01))`).

27.2.2 Improving our function

You might notice that the `rescale01()` function does some unnecessary work — instead of computing `min()` twice and `max()` once we could instead compute both the minimum and maximum in one step with `range()`:

```
rescale01 <- function(x) {  
  rng <- range(x, na.rm = TRUE)  
  (x - rng[1]) / (rng[2] - rng[1])  
}
```

Or you might try this function on a vector that includes an infinite value:

```
x <- c(1:10, Inf)  
rescale01(x)  
#> [1] 0 0 0 0 0 0 0 0 0 0 NaN
```

That result is not particularly useful so we could ask `range()` to ignore infinite values:

```
rescale01 <- function(x) {  
  rng <- range(x, na.rm = TRUE, finite = TRUE)  
  (x - rng[1]) / (rng[2] - rng[1])  
}  
  
rescale01(x)  
#> [1] 0.0000000 0.1111111 0.2222222 0.3333333 0.4444444  
#> [6] 0.7777778 0.8888889 1.0000000 Inf
```

These changes illustrate an important benefit of functions: because we've moved the repeated code into a function, we only need to make the change in one place.

27.2.3 Mutate functions

Now you've got the basic idea of functions, let's take a look at a whole bunch of examples. We'll start by looking at "mutate" functions,

i.e. functions that work well inside of `mutate()` and `filter()` because they return an output of the same length as the input.

Let's start with a simple variation of `rescale01()`. Maybe you want to compute the Z-score, rescaling a vector to have a mean of zero and a standard deviation of one:

```
z_score <- function(x) {  
  (x - mean(x, na.rm = TRUE)) / sd(x, na.rm = TRUE)  
}
```

Or maybe you want to wrap up a straightforward `case_when()` and give it a useful name. For example, this `clamp()` function ensures all values of a vector lie in between a minimum or a maximum:

```
clamp <- function(x, min, max) {  
  case_when(  
    x < min ~ min,  
    x > max ~ max,  
    .default = x  
  )  
}  
  
clamp(1:10, min = 3, max = 7)  
#> [1] 3 3 3 4 5 6 7 7 7 7
```

Or maybe you'd rather mark those values as NAs:

```
na_outside <- function(x, min, max) {  
  case_when(  
    x < min ~ NA,  
    x > max ~ NA,  
    .default = x  
  )  
}
```

```
na_outside(1:10, min = 3, max = 7)
#> [1] NA NA 3 4 5 6 7 NA NA NA
```

Of course functions don't just need to work with numeric variables. You might want to do some repeated string manipulation. Maybe you need to make the first character upper case:

```
first_upper <- function(x) {
  str_sub(x, 1, 1) <- str_to_upper(str_sub(x, 1, 1))
  x
}

first_upper("hello")
#> [1] "Hello"
```

Or maybe you want to strip percent signs, commas, and dollar signs from a string before converting it into a number:

```
# https://twitter.com/NVlabormarket/status/1571939851922
clean_number <- function(x) {
  is_pct <- str_detect(x, "%")
  num <- x |>
    str_remove_all("%") |>
    str_remove_all(",") |>
    str_remove_all(fixed("$")) |>
    as.numeric(x)
  ifelse(is_pct, num / 100, num)
}

clean_number("$12,300")
#> [1] 12300
clean_number("45%")
#> [1] 0.45
```

Sometimes your functions will be highly specialized for one data analysis step. For example, if you have a bunch of variables that record missing values as 997, 998, or 999, you might want to write a function to replace them with NA :

```
fix_na <- function(x) {  
  if_else(x %in% c(997, 998, 999), NA, x)  
}
```

We've focused on examples that take a single vector because we think they're the most common. But there's no reason that your function can't take multiple vector inputs. For example, you might want to compute the distance between two locations on the globe using the haversine formula. This requires four vectors:

```
# https://twitter.com/RosanaFerrero/status/1574722120428  
haversine <- function(long1, lat1, long2, lat2, round =  
  # convert to radians  
  long1 <- long1 * pi / 180  
  lat1 <- lat1 * pi / 180  
  long2 <- long2 * pi / 180  
  lat2 <- lat2 * pi / 180  
  
  R <- 6371 # Earth mean radius in km  
  a <- sin((lat2 - lat1) / 2)^2 +  
    cos(lat1) * cos(lat2) * sin((long2 - long1) / 2)^2  
  d <- R * 2 * asin(sqrt(a))  
  
  round(d, round)  
}
```

27.2.4 Summary functions

Another important family of vector functions is summary functions, functions that return a single value for use in `summarize()`. Sometimes this can just be a matter of setting a default argument or two:

```
commas <- function(x) {  
  str_flatten(x, collapse = ", ", last = " and ")  
}  
  
commas(c("cat", "dog", "pigeon"))  
#> [1] "cat, dog and pigeon"
```

Or you might wrap up a simple computation, like for the coefficient of variation, which divides the standard deviation by the mean:

```
cv <- function(x, na.rm = FALSE) {  
  sd(x, na.rm = na.rm) / mean(x, na.rm = na.rm)  
}  
  
cv(runif(100, min = 0, max = 50))  
#> [1] 0.5196276  
cv(runif(100, min = 0, max = 500))  
#> [1] 0.5652554
```

Or maybe you just want to make a common pattern easier to remember by giving it a memorable name:

```
# https://twitter.com/gbganalyst/status/1571619641390252  
n_missing <- function(x) {  
  sum(is.na(x))  
}
```

You can also write functions with multiple vector inputs. For example, maybe you want to compute the mean absolute prediction error to help

you compare model predictions with actual values:

```
# https://twitter.com/neilgcurrie/status/157160772725583
mape <- function(actual, predicted) {
  sum(abs((actual - predicted) / actual)) / length(actual)
```

RStudio

Once you start writing functions, there are two RStudio shortcuts that are super useful:

- To find the definition of a function that you've written, place the cursor on the name of the function and press F2.
- To quickly jump to a function, press Ctrl + . to open the fuzzy file and function finder and type the first few letters of your function name. You can also navigate to files, Quarto sections, and more, making it a very handy navigation tool.

27.2.5 Exercises

1. Practice turning the following code snippets into functions. Think about what each function does. What would you call it? How many arguments does it need?

```
mean(is.na(x))
mean(is.na(y))
mean(is.na(z))

x / sum(x, na.rm = TRUE)
y / sum(y, na.rm = TRUE)
z / sum(z, na.rm = TRUE)
```

```
round(x / sum(x, na.rm = TRUE) * 100, 1)
round(y / sum(y, na.rm = TRUE) * 100, 1)
round(z / sum(z, na.rm = TRUE) * 100, 1)
```

2. In the second variant of `rescale01()`, infinite values are left unchanged. Can you rewrite `rescale01()` so that `-Inf` is mapped to 0, and `Inf` is mapped to 1?
3. Given a vector of birthdates, write a function to compute the age in years.
4. Write your own functions to compute the variance and skewness of a numeric vector. Variance is defined as
$$\text{Var}(x) = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2,$$
where $\bar{x} = (\sum_i^n x_i)/n$ is the sample mean. Skewness is defined as
$$\text{Skew}(x) = \frac{\frac{1}{n-2} (\sum_{i=1}^n (x_i - \bar{x})^3)}{\text{Var}(x)^{3/2}}.$$
5. Write `both_na()`, a summary function that takes two vectors of the same length and returns the number of positions that have an `NA` in both vectors.
6. Read the documentation to figure out what the following functions do. Why are they useful even though they are so short?

```
is_directory <- function(x) file.info(x)$isdir
is_readable <- function(x) file.access(x, 4) == 0
```

27.3 Data frame functions

Vector functions are useful for pulling out code that's repeated within a dplyr verb. But you'll often also repeat the verbs themselves, particularly within a large pipeline. When you notice yourself copying and pasting multiple verbs multiple times, you might think about writing a data frame function. Data frame functions work like dplyr verbs: they take a data frame as the first argument, some extra arguments that say what to do with it, and return a data frame or vector.

To let you write a function that uses dplyr verbs, we'll first introduce you to the challenge of indirection and how you can overcome it with embracing, `{} {}`. With this theory under your belt, we'll then show you a bunch of examples to illustrate what you might do with it.

27.3.1 Indirection and tidy evaluation

When you start writing functions that use dplyr verbs you rapidly hit the problem of indirection. Let's illustrate the problem with a very simple function: `grouped_mean()`. The goal of this function is compute the mean of `mean_var` grouped by `group_var`:

```
grouped_mean <- function(df, group_var, mean_var) {  
  df |>  
    group_by(group_var) |>  
    summarize(mean(mean_var))  
}
```

If we try and use it, we get an error:

```
diamonds |> grouped_mean(cut, carat)  
#> Error in `group_by()`:
```

```
#> ! Must group by variables found in `data`.  
#> ✘ Column `group_var` is not found.
```

To make the problem a bit more clear, we can use a made up data frame:

```
df <- tibble(  
  mean_var = 1,  
  group_var = "g",  
  group = 1,  
  x = 10,  
  y = 100  
)  
  
df |> grouped_mean(group, x)  
#> # A tibble: 1 × 2  
#>   group_var `mean(mean_var)`  
#>   <chr>           <dbl>  
#>   g                 1  
df |> grouped_mean(group, y)  
#> # A tibble: 1 × 2  
#>   group_var `mean(mean_var)`  
#>   <chr>           <dbl>  
#>   g                 1
```

Regardless of how we call `grouped_mean()` it always does `df |> group_by(group_var) |> summarize(mean(mean_var))`, instead of `df |> group_by(group) |> summarize(mean(x))` or `df |> group_by(group) |> summarize(mean(y))`. This is a problem of indirection, and it arises because dplyr uses **tidy evaluation** to allow you to refer to the names of variables inside your data frame without any special treatment.

Tidy evaluation is great 95% of the time because it makes your data analyses very concise as you never have to say which data frame a variable comes from; it's obvious from the context. The downside of tidy evaluation comes when we want to wrap up repeated tidyverse code

into a function. Here we need some way to tell `group_mean()` and `summarize()` not to treat `group_var` and `mean_var` as the name of the variables, but instead look inside them for the variable we actually want to use.

Tidy evaluation includes a solution to this problem called **embracing** 😊. Embracing a variable means to wrap it in braces so (e.g.) `var` becomes `{{ var }}`. Embracing a variable tells dplyr to use the value stored inside the argument, not the argument as the literal variable name. One way to remember what's happening is to think of `{}{ }` as looking down a tunnel — `{}{ var }` will make a dplyr function look inside of `var` rather than looking for a variable called `var`.

So to make `grouped_mean()` work, we need to surround `group_var` and `mean_var()` with `{}{ }`:

```
grouped_mean <- function(df, group_var, mean_var) {  
  df |>  
    group_by({{ group_var }}) |>  
    summarize(mean({{ mean_var }}))  
}  
  
diamonds |> grouped_mean(cut, carat)  
#> # A tibble: 5 × 2  
#>   cut      `mean(carat)`  
#>   <ord>        <dbl>  
#> 1 Fair          1.05  
#> 2 Good         0.849  
#> 3 Very Good    0.806  
#> 4 Premium       0.892  
#> 5 Ideal         0.703
```

Success!

27.3.2 When to embrace?

So the key challenge in writing data frame functions is figuring out which arguments need to be embraced. Fortunately, this is easy because you can look it up from the documentation 😊 . There are two terms to look for in the docs which correspond to the two most common sub-types of tidy evaluation:

- **Data-masking**: this is used in functions like `arrange()`, `filter()`, and `summarize()` that compute with variables.
- **Tidy-selection**: this is used for functions like `select()`, `relocate()`, and `rename()` that select variables.

Your intuition about which arguments use tidy evaluation should be good for many common functions — just think about whether you can compute (e.g. `x + 1`) or select (e.g. `a:x`).

In the following sections, we'll explore the sorts of handy functions you might write once you understand embracing.

27.3.3 Common use cases

If you commonly perform the same set of summaries when doing initial data exploration, you might consider wrapping them up in a helper function:

```
summary6 <- function(data, var) {  
  data |> summarize(  
    min = min({{ var }}), na.rm = TRUE),  
    mean = mean({{ var }}), na.rm = TRUE),  
    median = median({{ var }}), na.rm = TRUE),  
    max = max({{ var }}), na.rm = TRUE),  
    n = n(),
```

```
n_miss = sum(is.na({{ var }})),  
  .groups = "drop"  
)  
}  
  
diamonds |> summary6(carat)  
#> # A tibble: 1 × 6  
#>   min   mean median   max     n n_miss  
#> <dbl> <dbl>  <dbl> <dbl> <int> <int>  
#> 1   0.2  0.798    0.7  5.01  53940      0
```

(Whenever you wrap `summarize()` in a helper, we think it's good practice to set `.groups = "drop"` to both avoid the message and leave the data in an ungrouped state.)

The nice thing about this function is, because it wraps `summarize()`, you can use it on grouped data:

```
diamonds |>  
  group_by(cut) |>  
  summary6(carat)  
#> # A tibble: 5 × 7  
#>   cut      min   mean median   max     n n_miss  
#> <ord>    <dbl> <dbl>  <dbl> <dbl> <int> <int>  
#> 1 Fair     0.22  1.05    1    5.01  1610      0  
#> 2 Good     0.23  0.849   0.82  3.01  4906      0  
#> 3 Very Good 0.2   0.806   0.71   4    12082      0  
#> 4 Premium   0.2   0.892   0.86   4.01  13791      0  
#> 5 Ideal     0.2   0.703   0.54   3.5   21551      0
```

Furthermore, since the arguments to `summarize` are data-masking also means that the `var` argument to `summary6()` is data-masking. That means you can also summarize computed variables:

```
diamonds |>  
  group_by(cut) |>
```

```
summary6(log10(carat))  
#> # A tibble: 5 × 7  
#>   cut      min    mean   median    max     n n_miss  
#>   <ord>    <dbl>  <dbl>   <dbl>  <dbl> <int>  <int>  
#> 1 Fair     -0.658 -0.0273  0       0.700  1610     0  
#> 2 Good     -0.638 -0.133   -0.0862 0.479  4906     0  
#> 3 Very Good -0.699 -0.164   -0.149  0.602 12082     0  
#> 4 Premium   -0.699 -0.125   -0.0655 0.603 13791     0  
#> 5 Ideal     -0.699 -0.225   -0.268  0.544 21551     0
```

To summarize multiple variables, you'll need to wait until [Section 28.2](#), where you'll learn how to use `across()`.

Another popular `summarize()` helper function is a version of `count()` that also computes proportions:

```
# https://twitter.com/Diabb6/status/1571635146658402309  
count_prop <- function(df, var, sort = FALSE) {  
  df |>  
    count({{ var }}, sort = sort) |>  
    mutate(prop = n / sum(n))  
}  
  
diamonds |> count_prop(clarity)  
#> # A tibble: 8 × 3  
#>   clarity     n     prop  
#>   <ord>    <int>  <dbl>  
#> 1 I1         741  0.0137  
#> 2 SI2        9194 0.170  
#> 3 SI1       13065 0.242  
#> 4 VS2        12258 0.227  
#> 5 VS1        8171  0.151  
#> 6 VVS2       5066  0.0939  
#> # ... with 2 more rows
```

This function has three arguments: `df`, `var`, and `sort`, and only `var` needs to be embraced because it's passed to `count()` which uses data-masking for all variables in `...`.

Or maybe you want to find the sorted unique values of a variable for a subset of the data. Rather than supplying a variable and a value to do the filtering, we'll allow the user to supply a condition:

```
unique_where <- function(df, condition, var) {  
  df |>  
    filter({{ condition }}) |>  
    distinct({{ var }}) |>  
    arrange({{ var }})  
}  
  
# Find all the destinations in December  
flights |> unique_where(month == 12, dest)  
#> # A tibble: 96 × 1  
#>   dest  
#>   <chr>  
#> 1 ABQ  
#> 2 ALB  
#> 3 ATL  
#> 4 AUS  
#> 5 AVL  
#> 6 BDL  
#> # ... with 90 more rows  
# Which months did plane N14228 fly in?  
flights |> unique_where(tailnum == "N14228", month)  
#> # A tibble: 11 × 1  
#>   month  
#>   <int>  
#> 1     1  
#> 2     2  
#> 3     3  
#> 4     4
```

```
#> 5      5  
#> 6      6  
#> # ... with 5 more rows
```

Here we embrace condition because it's passed to `filter()` and `var` because it's passed to `distinct()` and `arrange()`.

We've made all these examples to take a data frame as the first argument, but if you're working repeatedly with the same data, it can make sense to hardcode it. For example, the following function always works with the flights dataset and always selects `time_hour`, `carrier`, and `flight` since they form the compound primary key that allows you to identify a row.

```
flights_sub <- function(rows, cols) {  
  flights |>  
    filter({{ rows }}) |>  
    select(time_hour, carrier, flight, {{ cols }})  
}  
  
flights_sub(dest == "IAH", contains("time"))  
#> # A tibble: 7,198 × 8  
#>   time_hour           carrier flight dep_time sched...¹  
#>   <dttm>             <chr>    <int>    <int>    <int>  
#> 1 2013-01-01 05:00:00 UA        1545      517      515  
#> 2 2013-01-01 05:00:00 UA        1714      533      529  
#> 3 2013-01-01 06:00:00 UA        496       623      627  
#> 4 2013-01-01 07:00:00 UA        473       728      732  
#> 5 2013-01-01 07:00:00 UA       1479      739      739  
#> 6 2013-01-01 09:00:00 UA       1220      908      908  
#> # ... with 7,192 more rows, and abbreviated variable na  
#> #   ^arr_time, ^sched_arr_time, ^air_time
```

27.3.4 Data-masking vs. tidy-selection

Sometimes you want to select variables inside a function that uses data-masking. For example, imagine you want to write a `count_missing()` that counts the number of missing observations in rows. You might try writing something like:

```
count_missing <- function(df, group_vars, x_var) {  
  df |>  
    group_by({{ group_vars }}) |>  
    summarize(n_miss = sum(is.na({{ x_var }})))  
}  
  
flights |>  
  count_missing(c(year, month, day), dep_time)  
#> Error in `group_by()`:  
#> i In argument: `c(year, month, day)`.  
#> Caused by error:  
#> ! `c(year, month, day)` must be size 336776 or 1, not
```

This doesn't work because `group_by()` uses data-masking, not tidy-selection. We can work around that problem by using the handy `pick()` function, which allows you to use tidy-selection inside data-masking functions:

```
count_missing <- function(df, group_vars, x_var) {  
  df |>  
    group_by(pick({{ group_vars }})) |>  
    summarize(n_miss = sum(is.na({{ x_var }})))  
}  
  
flights |>  
  count_missing(c(year, month, day), dep_time)  
#> `summarise()` has grouped output by 'year', 'month'.  
#> the `groups` argument.  
#> # A tibble: 365 × 4
```

```

#> # Groups: year, month [12]
#>   year month   day n_miss
#>   <int> <int> <int> <int>
#> 1 2013     1     1     4
#> 2 2013     1     2     8
#> 3 2013     1     3    10
#> 4 2013     1     4     6
#> 5 2013     1     5     3
#> 6 2013     1     6     1
#> # ... with 359 more rows

```

Another convenient use of `pick()` is to make a 2d table of counts. Here we count using all the variables in the `rows` and `columns`, then use `pivot_wider()` to rearrange the counts into a grid:

```

# https://twitter.com/pollicipes/status/1571606508944719
count_wide <- function(data, rows, cols) {
  data |>
    count(pick(c({{ rows }}, {{ cols }}))) |>
    pivot_wider(
      names_from = {{ cols }},
      values_from = n,
      names_sort = TRUE,
      values_fill = 0
    )
}

diamonds |> count_wide(clarity, cut)
#> # A tibble: 8 × 6
#>   clarity Fair Good `Very Good` Premium Ideal
#>   <ord>   <int> <int>       <int>   <int> <int>
#> 1 I1        210   96          84     205   146
#> 2 SI2       466  1081        2100    2949  2598
#> 3 SI1       408  1560        3240    3575  4282
#> 4 VS2       261   978        2591    3357  5071

```

```

#> 5 VS1      170   648      1775   1989   3589
#> 6 VVS2      69    286      1235   870    2606
#> # ... with 2 more rows
diamonds |> count_wide(c(clarity, color), cut)
#> # A tibble: 56 × 7
#>   clarity color  Fair  Good `Very Good` Premium Ideal
#>   <ord>    <ord> <int> <int>        <int>   <int> <int>
#> 1 I1       D     4     8       5     12    13
#> 2 I1       E     9    23      22     30    18
#> 3 I1       F    35    19      13     34    42
#> 4 I1       G    53    19      16     46    16
#> 5 I1       H    52    14      12     46    38
#> 6 I1       I    34     9       8     24    17
#> # ... with 50 more rows

```

While our examples have mostly focused on dplyr, tidy evaluation also underpins tidyr, and if you look at the `pivot_wider()` docs you can see that `names_from` uses tidy-selection.

27.3.5 Exercises

1. Using the datasets from nycflights13, write a function that:
 1. Finds all flights that were cancelled (i.e. `is.na(arr_time)`) or delayed by more than an hour.

```
flights |> filter_severe()
```

2. Counts the number of cancelled flights and the number of flights delayed by more than an hour.

```
flights |> group_by(dest) |> summarize_severe()
```

3. Finds all flights that were cancelled or delayed by more than a user supplied number of hours:

```
flights |> filter_severe(hours = 2)
```

4. Summarizes the weather to compute the minimum, mean, and maximum, of a user supplied variable:

```
weather |> summarize_weather(temp)
```

5. Converts the user supplied variable that uses clock time (e.g. `dep_time`, `arr_time`, etc.) into a decimal time (i.e. $\text{hours} + (\text{minutes} / 60)$).

```
weather |> standardise_time(sched_dep_time)
```

2. For each of the following functions list all arguments that use tidy evaluation and describe whether they use data-masking or tidy-selection: `distinct()`, `count()`, `group_by()`, `rename_with()`, `slice_min()`, `slice_sample()`.

3. Generalize the following function so that you can supply any number of variables to count.

```
count_prop <- function(df, var, sort = FALSE) {  
  df |>  
    count('{{ var }}', sort = sort) |>  
    mutate(prop = n / sum(n))  
}
```

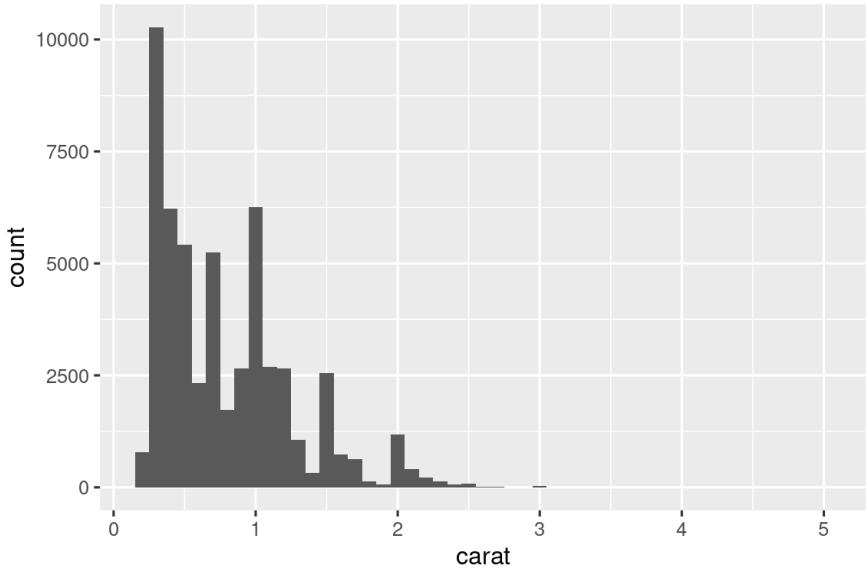

27.4 Plot functions

Instead of returning a data frame, you might want to return a plot. Fortunately, you can use the same techniques with ggplot2, because `aes()` is a data-masking function. For example, imagine that you're making a lot of histograms:

```
diamonds |>  
  ggplot(aes(x = carat)) +  
  geom_histogram(binwidth = 0.1)  
  
diamonds |>  
  ggplot(aes(x = carat)) +  
  geom_histogram(binwidth = 0.05)
```

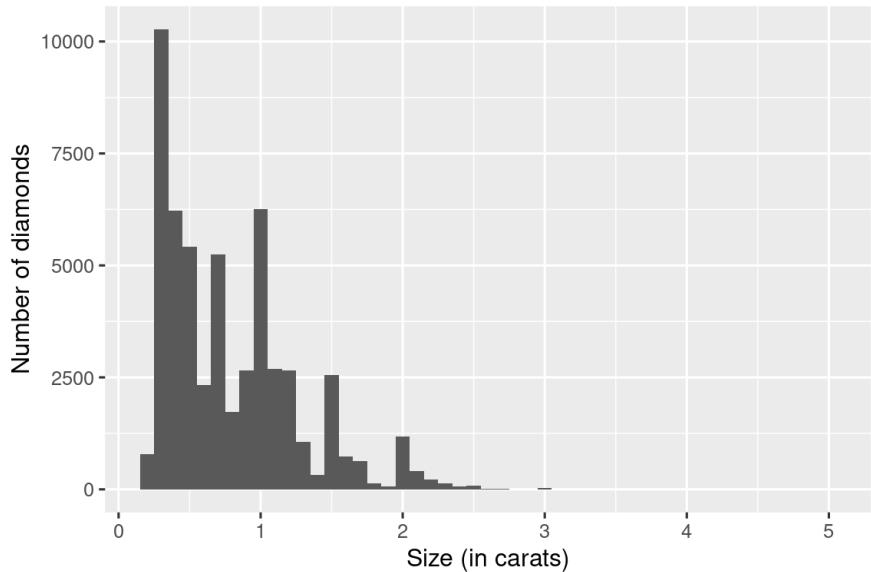

Wouldn't it be nice if you could wrap this up into a histogram function? This is easy as pie once you know that `aes()` is a data-masking function and you need to embrace:

```
histogram <- function(df, var, binwidth = NULL) {  
  df |>  
    ggplot(aes(x = {{ var }})) +  
    geom_histogram(binwidth = binwidth)  
}  
  
diamonds |> histogram(carat, 0.1)
```

Note that `histogram()` returns a ggplot2 plot, meaning you can still add on additional components if you want. Just remember to switch from `|>` to `:+`:

```
diamonds |>
  histogram(carat, 0.1) +
  labs(x = "Size (in carats)", y = "Number of diamonds")
```

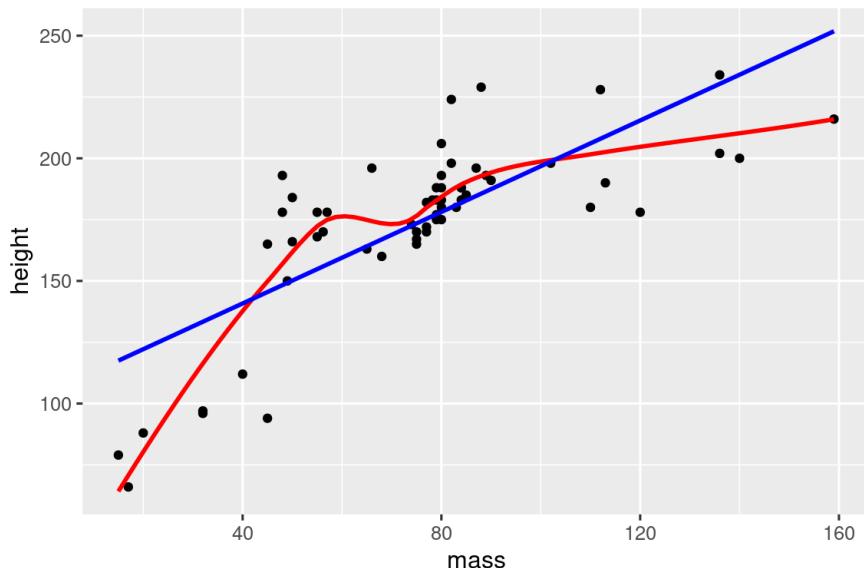

27.4.1 More variables

It's straightforward to add more variables to the mix. For example, maybe you want an easy way to eyeball whether or not a data set is linear by overlaying a smooth line and a straight line:

```
# https://twitter.com/tyler_js_smith/status/157437711698
linearity_check <- function(df, x, y) {
  df |>
    ggplot(aes(x = {{ x }}, y = {{ y }})) +
    geom_point() +
    geom_smooth(method = "loess", color = "red", se = FALSE) +
    geom_smooth(method = "lm", color = "blue", se = FALSE)
}

starwars |>
  filter(mass < 1000) |>
  linearity_check(mass, height)
```

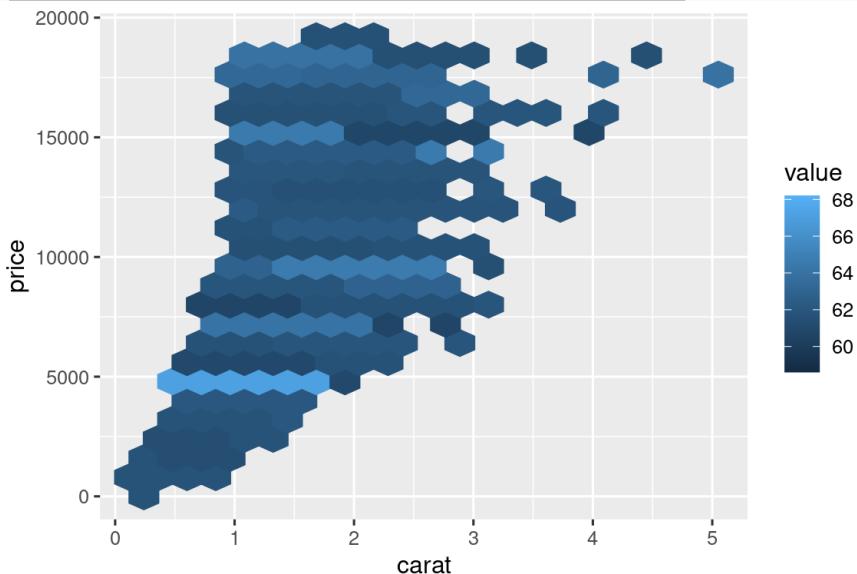

```
#> `geom_smooth()` using formula = 'y ~ x'  
#> `geom_smooth()` using formula = 'y ~ x'
```

Or maybe you want an alternative to colored scatterplots for very large datasets where overplotting is a problem:

```
# https://twitter.com/ppaxisa/status/1574398423175921665  
hex_plot <- function(df, x, y, z, bins = 20, fun = "mean"  
df |>  
  ggplot(aes(x = {{ x }}, y = {{ y }}, z = {{ z }})) +  
  stat_summary_hex(  
    aes(color = after_scale(fill)), # make border same  
    bins = bins,  
    fun = fun,  
  )  
}
```

```
diamonds |> hex_plot(carat, price, depth)
```

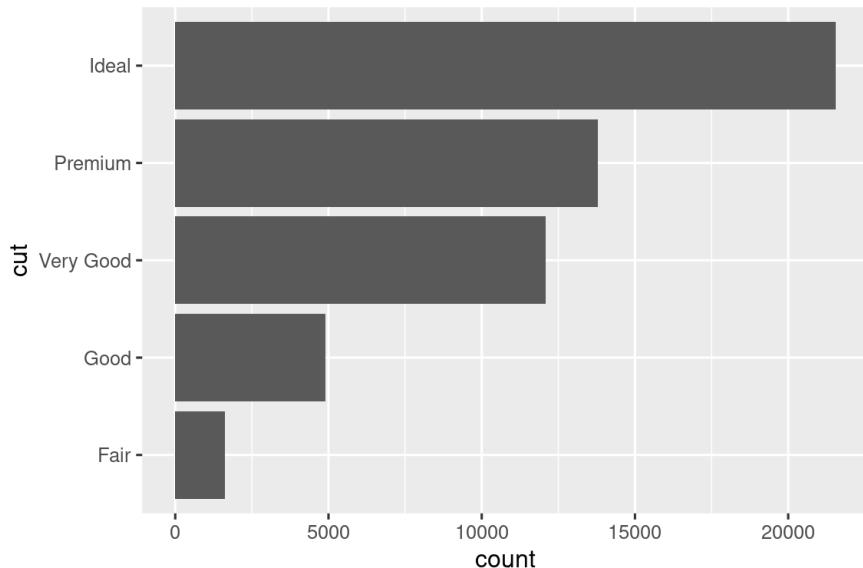

27.4.2 Combining with dplyr

Some of the most useful helpers combine a dash of dplyr with ggplot2. For example, if you might want to do a vertical bar chart where you automatically sort the bars in frequency order using `fct_infreq()`. Since the bar chart is vertical, we also need to reverse the usual order to get the highest values at the top:

```
sorted_bars <- function(df, var) {  
  df |>  
    mutate({{ var }} := fct_rev(fct_infreq({{ var }})))  
  ggplot(aes(y = {{ var }})) +  
    geom_bar()  
}
```

```
diamonds |> sorted_bars(cut)
```

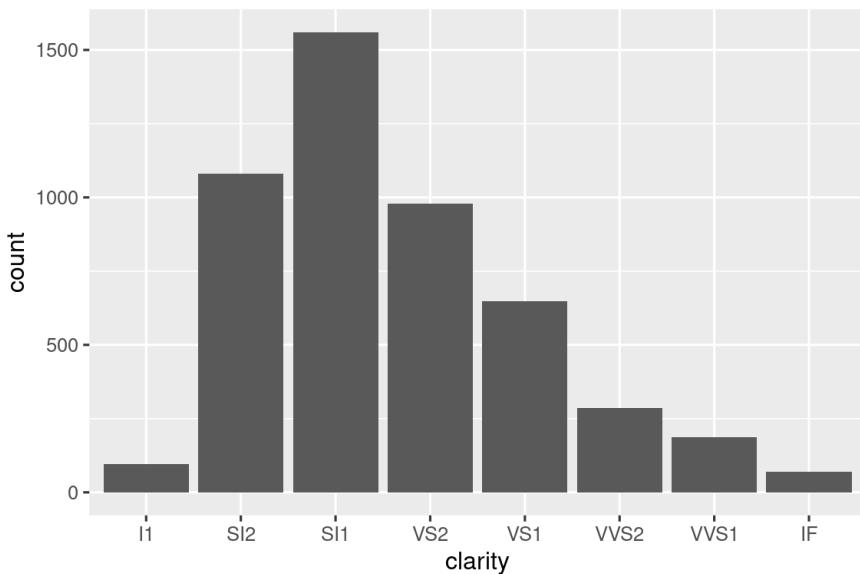

We have to use a new operator here, `:=`, because we are generating the variable name based on user-supplied data. Variable names go on the left hand side of `=`, but R's syntax doesn't allow anything to the left of `=` except for a single literal name. To work around this problem, we use the special operator `:=` which tidy evaluation treats in exactly the same way as `=`.

Or maybe you want to make it easy to draw a bar plot just for a subset of the data:

```
conditional_bars <- function(df, condition, var) {  
  df |>  
    filter({{ condition }}) |>  
    ggplot(aes(x = {{ var }})) +  
    geom_bar()
```

```
}
```

```
diamonds |> conditional_bars(cut == "Good", clarity)
```

You can also get creative and display data summaries in other ways. For example, this code uses the axis labels to display the highest value. As you learn more about ggplot2, the power of your functions will continue to increase.

```
# https://gist.github.com/GShotwell/b19ef520b6d56f61a83e
fancy_ts <- function(df, val, group) {
  labs <- df |>
    group_by({{ group }}) |>
    summarize(breaks = max({{ val }}))

  df |>
    ggplot(aes(x = date, y = {{ val }}), group = {{ group }})
      geom_path() +
      scale_y_continuous(
        breaks = labs$breaks,
```

```

    labels = scales::label_comma(),
    minor_breaks = NULL,
    guide = guide_axis(position = "right")
)
}

df <- tibble(
  dist1 = sort(rnorm(50, 5, 2)),
  dist2 = sort(rnorm(50, 8, 3)),
  dist4 = sort(rnorm(50, 15, 1)),
  date = seq.Date(as.Date("2022-01-01"), as.Date("2022-04-01"),
)
)

df <- pivot_longer(df, cols = -date, names_to = "dist_name",
  values_to = "value")

fancy_ts(df, value, dist_name)

```

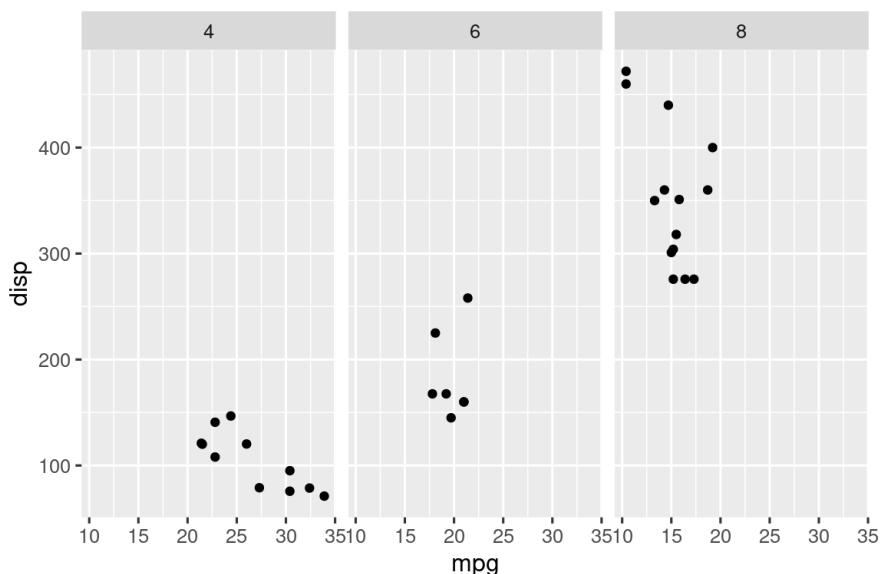

Next we'll discuss two more complicated cases: faceting and automatic labeling.

27.4.3 Faceting

Unfortunately, programming with faceting is a special challenge, because faceting was implemented before we understood what tidy evaluation was and how it should work. So you have to learn a new syntax. When programming with facets, instead of writing `~ x`, you need to write `vars(x)` and instead of `~ x + y` you need to write `vars(x, y)`. The only advantage of this syntax is that `vars()` uses tidy evaluation so you can embrace within it:

```
# https://twitter.com/sharoz/status/1574376332821204999
foo <- function(x) {
  ggplot(mtcars, aes(x = mpg, y = disp)) +
  geom_point() +
  facet_wrap(vars({{ x }}))
}

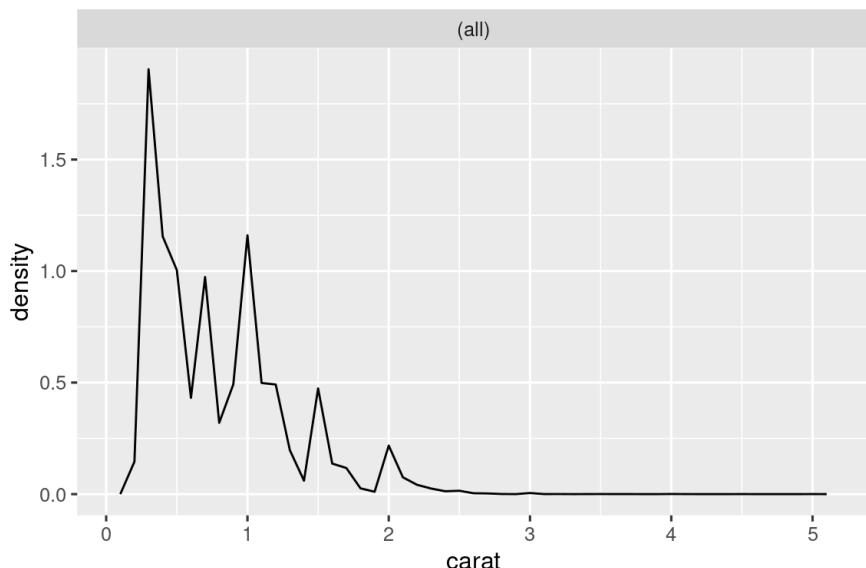

foo(cyl)
```

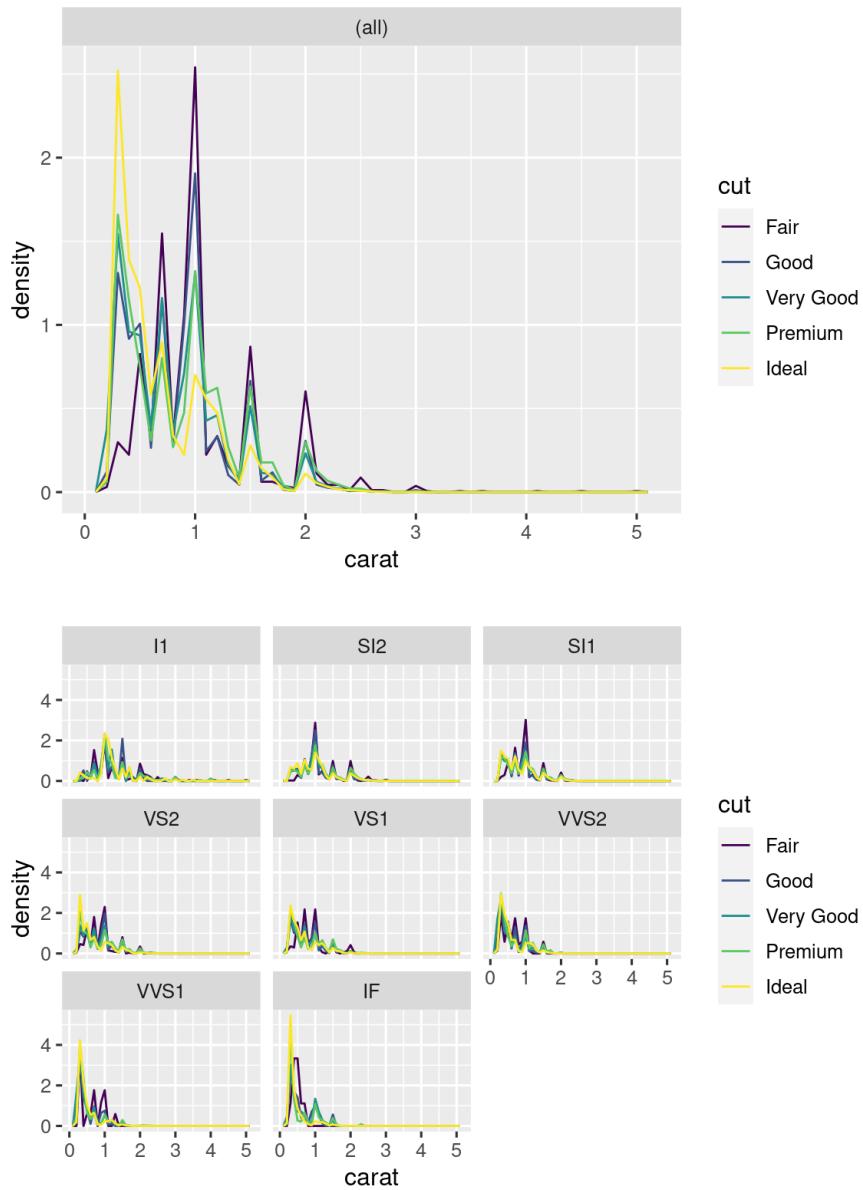

As with data frame functions, it can be useful to make your plotting functions tightly coupled to a specific dataset, or even a specific variable. For example, the following function makes it particularly easy to interactively explore the conditional distribution of `carat` from the diamonds dataset.

```
# https://twitter.com/yutannihilat_en/status/15743872306
density <- function(color, facets, binwidth = 0.1) {
  diamonds |>
    ggplot(aes(x = carat, y = after_stat(density), color =
      geom_freqpoly(binwidth = binwidth) +
      facet_wrap(vars({{ facets }}))
}

density()
density(cut)
density(cut, clarity)
```

27.4.4 Labeling

Remember the histogram function we showed you earlier?

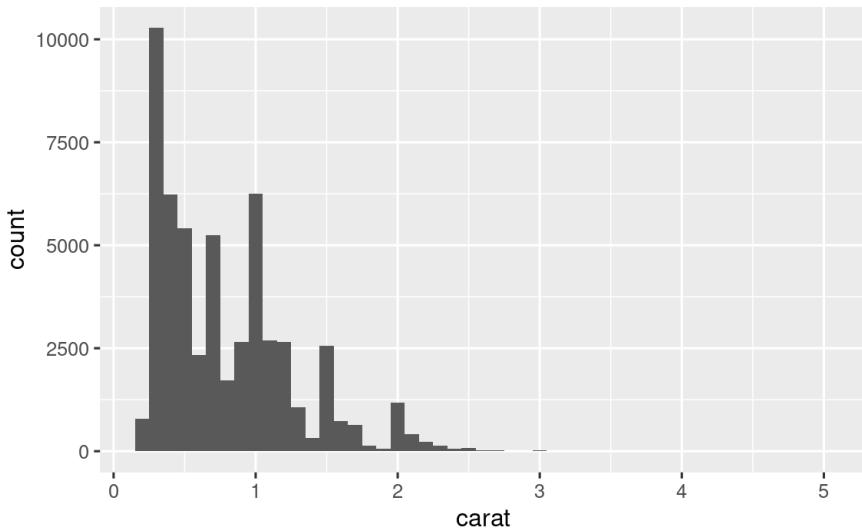

```
histogram <- function(df, var, binwidth = NULL) {  
  df |>  
    ggplot(aes(x = {{ var }})) +  
    geom_histogram(binwidth = binwidth)  
}
```

Wouldn't it be nice if we could label the output with the variable and the bin width that was used? To do so, we're going to have to go under the covers of tidy evaluation and use a function from the package we haven't talked about yet: rlang. rlang is a low-level package that's used by just about every other package in the tidyverse because it implements tidy evaluation (as well as many other useful tools).

To solve the labeling problem we can use `rlang::englue()`. This works similarly to `str_glue()`, so any value wrapped in `{ }` will be inserted into the string. But it also understands `{{ }}`, which automatically inserts the appropriate variable name:

```
histogram <- function(df, var, binwidth) {  
  label <- rlang::englue("A histogram of {{var}} with bi  
  
  df |>  
    ggplot(aes(x = {{ var }})) +  
    geom_histogram(binwidth = binwidth) +  
    labs(title = label)  
}  
  
diamonds |> histogram(carat, 0.1)
```

A histogram of carat with binwidth 0.1

You can use the same approach in any other place where you want to supply a string in a ggplot2 plot.

27.4.5 Exercises

Build up a rich plotting function by incrementally implementing each of the steps below:

1. Draw a scatterplot given dataset and `x` and `y` variables.
2. Add a line of best fit (i.e. a linear model with no standard errors).
3. Add a title.

27.5 Style

R doesn't care what your function or arguments are called but the names make a big difference for humans. Ideally, the name of your function will be short, but clearly evoke what the function does. That's

hard! But it's better to be clear than short, as RStudio's autocomplete makes it easy to type long names.

Generally, function names should be verbs, and arguments should be nouns. There are some exceptions: nouns are ok if the function computes a very well known noun (i.e. `mean()` is better than `compute_mean()`), or accessing some property of an object (i.e. `coef()` is better than `get_coefficients()`). Use your best judgement and don't be afraid to rename a function if you figure out a better name later.

```
# Too short
f()

# Not a verb, or descriptive
my_awesome_function()

# Long, but clear
impute_missing()
collapse_years()
```

R also doesn't care about how you use white space in your functions but future readers will. Continue to follow the rules from [Chapter 7](#). Additionally, `function()` should always be followed by squiggly brackets (`{}`), and the contents should be indented by an additional two spaces. This makes it easier to see the hierarchy in your code by skimming the left-hand margin.

```
# missing extra two spaces
density <- function(color, facets, binwidth = 0.1) {
  diamonds |>
    ggplot(aes(x = carat, y = after_stat(density), color =
      geom_freqpoly(binwidth = binwidth) +
      facet_wrap(vars({{ facets }})))
```

```
}  
  
# Pipe indented incorrectly  
density <- function(color, facets, binwidth = 0.1) {  
  diamonds |>  
  ggplot(aes(x = carat, y = after_stat(density), color =  
    geom_freqpoly(binwidth = binwidth) +  
    facet_wrap(vars({{ facets }})))  
}  
  
}
```

As you can see we recommend putting extra spaces inside of {{ }}. This makes it very obvious that something unusual is happening.

27.5.1 Exercises

1. Read the source code for each of the following two functions, puzzle out what they do, and then brainstorm better names.

```
f1 <- function(string, prefix) {  
  substr(string, 1, nchar(prefix)) == prefix  
}  
  
f3 <- function(x, y) {  
  rep(y, length.out = length(x))  
}
```

2. Take a function that you've written recently and spend 5 minutes brainstorming a better name for it and its arguments.
3. Make a case for why `norm_r()`, `norm_d()` etc. would be better than `rnorm()`, `dnorm()`. Make a case for the opposite.

27.6 Summary

In this chapter, you learned how to write functions for three useful scenarios: creating a vector, creating a data frames, or creating a plot. Along the way you saw many examples, which hopefully started to get your creative juices flowing, and gave you some ideas for where functions might help your analysis code.

We have only shown you the bare minimum to get started with functions and there's much more to learn. A few places to learn more are:

- To learn more about programming with tidy evaluation, see useful recipes in [programming with dplyr](#) and [programming with tidyverse](#) and learn more about the theory in [What is data-masking and why do I need {{?}}](#).
- To learn more about reducing duplication in your ggplot2 code, read the [Programming with ggplot2](#) chapter of the ggplot2 book.
- For more advice on function style, see the [tidyverse style guide](#).

In the next chapter, we'll dive into some of the details of R's vector data structures that we've omitted so far. These are not immediately useful by themselves, but are a necessary foundation for the following chapter on iteration which gives you further tools for reducing code duplication.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

28.1 Introduction

In this chapter, you’ll learn tools for iteration, repeatedly performing the same action on different objects. Iteration in R generally tends to look rather different from other programming languages because so much of it is implicit and we get it for free. For example, if you want to double a numeric vector `x` in R, you can just write `2 * x`. In most other languages, you’d need to explicitly double each element of `x` using some sort of for loop.

This book has already given you a small but powerful number of tools that perform the same action for multiple “things”:

- `facet_wrap()` and `facet_grid()` draws a plot for each subset.
- `group_by()` plus `summarize()` computes a summary statistics for each subset.
- `unnest_wider()` and `unnest_longer()` create new rows and columns for each element of a list-column.

Now it’s time to learn some more general tools, often called **functional programming** tools because they are built around functions that take other functions as inputs. Learning functional programming can easily veer into the abstract, but in this chapter we’ll keep things concrete by

focusing on three common tasks: modifying multiple columns, reading multiple files, and saving multiple objects.

28.1.1 Prerequisites

- ! This chapter relies on features only found in purrr 1.0.0 and dplyr 1.1.0, which are still in development. If you want to live life on the edge you can get the dev version with
- ```
devtools::install_github(c("tidyverse/purrr",
"tidyverse/dplyr")).
```

In this chapter, we'll focus on tools provided by dplyr and purrr, both core members of the tidyverse. You've seen dplyr before, but purrr is new. We're just going to use a couple of purrr functions in this chapter, but it's a great package to explore as you improve your programming skills.

```
library(tidyverse)
```

## 28.2 Modifying multiple columns

Imagine you have this simple tibble and you want to count the number of observations and compute the median of every column.

```
df <- tibble(
 a = rnorm(10),
 b = rnorm(10),
 c = rnorm(10),
 d = rnorm(10)
)
```

You could do it with copy-and-paste:

```
df |> summarize(
 n = n(),
 a = median(a),
 b = median(b),
 c = median(c),
 d = median(d),
)
#> # A tibble: 1 × 5
#> n a b c d
#> <int> <dbl> <dbl> <dbl> <dbl>
#> 1 10 -0.246 -0.287 -0.0567 0.144
```

That breaks our rule of thumb to never copy and paste more than twice, and you can imagine that this will get very tedious if you have tens or even hundreds of columns. Instead, you can use `across()`:

```
df |> summarize(
 n = n(),
 across(a:d, median),
)
#> # A tibble: 1 × 5
#> n a b c d
#> <int> <dbl> <dbl> <dbl> <dbl>
#> 1 10 -0.246 -0.287 -0.0567 0.144
```

`across()` has three particularly important arguments, which we'll discuss in detail in the following sections. You'll use the first two every time you use `across()`: the first argument, `.cols`, specifies which columns you want to iterate over, and the second argument, `.fns`, specifies what to do with each column. You can use the `.names` argument when you need additional control over the names of output columns, which is particularly important when you use `across()` with

`mutate()`. We'll also discuss two important variations, `if_any()` and `if_all()`, which work with `filter()`.

### 28.2.1 Selecting columns with `.cols`

The first argument to `across()`, `.cols`, selects the columns to transform. This uses the same specifications as `select()`, [Section 4.3.2](#), so you can use functions like `starts_with()` and `ends_with()` to select columns based on their name.

There are two additional selection techniques that are particularly useful for `across()`: `everything()` and `where()`. `everything()` is straightforward: it selects every (non-grouping) column:

```
df <- tibble(
 grp = sample(2, 10, replace = TRUE),
 a = rnorm(10),
 b = rnorm(10),
 c = rnorm(10),
 d = rnorm(10)
)

df |>
 group_by(grp) |>
 summarize(across(everything(), median))
#> # A tibble: 2 × 5
#> grp a b c d
#> <int> <dbl> <dbl> <dbl> <dbl>
#> 1 1 -0.0935 -0.0163 0.363 0.364
#> 2 2 0.312 -0.0576 0.208 0.565
```

Note grouping columns (`grp` here) are not included in `across()`, because they're automatically preserved by `summarize()`.

`where()` allows you to select columns based on their type:

- `where(is.numeric)` selects all numeric columns.
- `where(is.character)` selects all string columns.
- `where(is.Date)` selects all date columns.
- `where(is.POSIXct)` selects all date-time columns.
- `where(is.logical)` selects all logical columns.

```
df_types <- tibble(
 x1 = 1:3,
 x2 = runif(3),
 y1 = sample(letters, 3),
 y2 = c("banana", "apple", "egg")
)

df_types |>
 summarize(across(where(is.numeric), mean))
#> # A tibble: 1 × 2
#> x1 x2
#> <dbl> <dbl>
#> 1 2 0.370

df_types |>
 summarize(across(where(is.character), str_flatten()))
#> # A tibble: 1 × 2
#> y1 y2
#> <chr> <chr>
#> 1 kjh bananaappleegg
```

Just like other selectors, you can combine these with Boolean algebra. For example, `!where(is.numeric)` selects all non-numeric columns, and `starts_with("a") & where(is.logical)` selects all logical columns whose name starts with “a”.

## 28.2.2 Calling a single function

The second argument to `across()` defines how each column will be transformed. In simple cases, as above, this will be a single existing function. This is a pretty special feature of R: we're passing one function (`median`, `mean`, `str_flatten`, ...) to another function (`across`). This is one of the features that makes R a functional programming language.

It's important to note that we're passing this function to `across()`, so `across()` can call it, not calling it ourselves. That means the function name should never be followed by `()`. If you forget, you'll get an error:

```
df |>
 group_by(grp) |>
 summarize(across(everything(), median()))
#> Error in `summarize()`:
#> i In argument: `across(everything(), median())`.
#> Caused by error in `is.factor()`:
#> ! argument "x" is missing, with no default
```

This error arises because you're calling the function with no input, e.g.:

```
median()
#> Error in is.factor(x): argument "x" is missing, with
```

### 28.2.3 Calling multiple functions

In more complex cases, you might want to supply additional arguments or perform multiple transformations. Let's motivate this problem with a simple example: what happens if we have some missing values in our data? `median()` propagates those missing values, giving us a suboptimal output:

```

rnorm_na <- function(n, n_na, mean = 0, sd = 1) {
 sample(c(rnorm(n - n_na, mean = mean, sd = 1), rep(NA,
}

df_miss <- tibble(
 a = rnorm_na(5, 1),
 b = rnorm_na(5, 1),
 c = rnorm_na(5, 2),
 d = rnorm(5)
)
df_miss |>
 summarize(
 across(a:d, median),
 n = n()
)
#> # A tibble: 1 × 5
#> a b c d n
#> <dbl> <dbl> <dbl> <dbl> <int>
#> 1 NA NA NA 0.704 5

```

It would be nice if we could pass along `na.rm = TRUE` to `median()` to remove these missing values. To do so, instead of calling `median()` directly, we need to create a new function that calls `median()` with the desired arguments:

```

df_miss |>
 summarize(
 across(a:d, function(x) median(x, na.rm = TRUE)),
 n = n()
)
#> # A tibble: 1 × 5
#> a b c d n
#> <dbl> <dbl> <dbl> <dbl> <int>
#> 1 NA NA NA 0.704 5

```

```
#> <dbl> <dbl> <dbl> <dbl> <int>
#> 1 0.429 -0.721 -0.796 0.704 5
```

This is a little verbose, so R comes with a handy shortcut: for this sort of throw away, or **anonymous**<sup>1</sup>, function you can replace `function` with `\`<sup>2</sup>:

```
df_miss |>
 summarize(
 across(a:d, \((x) median(x, na.rm = TRUE)),

 n = n()
)
```

In either case, `across()` effectively expands to the following code:

```
df_miss |>
 summarize(
 a = median(a, na.rm = TRUE),
 b = median(b, na.rm = TRUE),
 c = median(c, na.rm = TRUE),
 d = median(d, na.rm = TRUE),
 n = n()
)
```

When we remove the missing values from the `median()`, it would be nice to know just how many values were removed. We can find that out by supplying two functions to `across()`: one to compute the median and the other to count the missing values. You supply multiple functions by using a named list to `.fns`:

```
df_miss |>
 summarize(
 across(a:d, list(
 median = \((x) median(x, na.rm = TRUE)),
 n_miss = \((x) sum(is.na(x))
))
```

```
)),
 n = n()
)

#> # A tibble: 1 × 9
#> a_median a_n_miss b_median b_n_miss c_median c_n_mi
#> <dbl> <int> <dbl> <int> <dbl> <int>
#> 1 0.429 1 -0.721 1 -0.796
#> # ... with abbreviated variable names `¹d_median, `²d_n_mi
```

If you look carefully, you might intuit that the columns are named using using a glue specification ([Section 16.3.2](#)) like `{.col}_{.fn}` where `.col` is the name of the original column and `.fn` is the name of the function. That's not a coincidence! As you'll learn in the next section, you can use `.names` argument to supply your own glue spec.

## 28.2.4 Column names

The result of `across()` is named according to the specification provided in the `.names` argument. We could specify our own if we wanted the name of the function to come first<sup>3</sup>:

```
df_miss |>
 summarize(
 across(
 a:d,
 list(
 median = \((x) median(x, na.rm = TRUE),
 n_miss = \((x) sum(is.na(x))
),
 .names = "{.fn}_{.col}"
),
 n = n(),
)
)
#> # A tibble: 1 × 9
#> median_a n_miss_a median_b n_miss_b median_c n_miss
```

```
#> <dbl> <int> <dbl> <int> <dbl> <in
#> 1 0.429 1 -0.721 1 -0.796
#> # ... with abbreviated variable names ¹median_d, ²n_mis
```

The `.names` argument is particularly important when you use `across()` with `mutate()`. By default, the output of `across()` is given the same names as the inputs. This means that `across()` inside of `mutate()` will replace existing columns. For example, here we use `coalesce()` to replace NAs with 0:

```
df_miss |>
 mutate(
 across(a:d, \((x) coalesce(x, 0)))
)
#> # A tibble: 5 × 4
#> a b c d
#> 1 0 -0.463 0 2.13
#> 2 -0.382 -0.980 0 0.704
#> 3 0.434 0 -1.06 0.715
#> 4 1.06 1.21 -0.796 -1.09
#> 5 0.424 -1.28 -0.785 0.402
```

If you'd like to instead create new columns, you can use the `.names` argument to give the output new names:

```
df_miss |>
 mutate(
 across(a:d, \((x) abs(x), .names = ".col_abs"))
)
#> # A tibble: 5 × 8
#> a b c d a_abs b_abs c_abs d_
#> 1 NA -0.463 NA 2.13 NA 0.463 NA 2.
```

```
#> 2 -0.382 -0.980 NA 0.704 0.382 0.980 NA 0.
#> 3 0.434 NA -1.06 0.715 0.434 NA 1.06 0.
#> 4 1.06 1.21 -0.796 -1.09 1.06 1.21 0.796 1.
#> 5 0.424 -1.28 -0.785 0.402 0.424 1.28 0.785 0.
```

## 28.2.5 Filtering

`across()` is a great match for `summarize()` and `mutate()` but it's more awkward to use with `filter()`, because you usually combine multiple conditions with either `|` or `&`. It's clear that `across()` can help to create multiple logical columns, but then what? So dplyr provides two variants of `across()` called `if_any()` and `if_all()`:

```
df_miss |> filter(is.na(a) | is.na(b) | is.na(c) | is.na(d))
#> # A tibble: 3 × 4
#> a b c d
#> <dbl> <dbl> <dbl> <dbl>
#> 1 NA -0.463 NA 2.13
#> 2 -0.382 -0.980 NA 0.704
#> 3 0.434 NA -1.06 0.715

same as:
df_miss |> filter(if_any(a:d, is.na))
#> # A tibble: 3 × 4
#> a b c d
#> <dbl> <dbl> <dbl> <dbl>
#> 1 NA -0.463 NA 2.13
#> 2 -0.382 -0.980 NA 0.704
#> 3 0.434 NA -1.06 0.715

df_miss |> filter(is.na(a) & is.na(b) & is.na(c) & is.na(d))
#> # A tibble: 0 × 4
#> # ... with 4 variables: a <dbl>, b <dbl>, c <dbl>, d <dbl>
same as:
df_miss |> filter(if_all(a:d, is.na))
```

```
#> # A tibble: 0 × 4
#> # ... with 4 variables: a <dbl>, b <dbl>, c <dbl>, d <dbl>
```

## 28.2.6 `across()` in functions

`across()` is particularly useful to program with because it allows you to operate on multiple columns. For example, [Jacob Scott](#) uses this little helper which wraps a bunch of lubridate function to expand all date columns into year, month, and day columns:

```
library(lubridate)
#> Loading required package: timechange
#>
#> Attaching package: 'lubridate'
#> The following objects are masked from 'package:base':
#>
#> date, intersect, setdiff, union

expand_dates <- function(df) {
 df |>
 mutate(
 across(where(is.Date), list(year = year,
 month = month,
 day = day)))
}

df_date <- tibble(
 name = c("Amy", "Bob"),
 date = ymd(c("2009-08-03", "2010-01-16"))
)

df_date |>
 expand_dates()
#> # A tibble: 2 × 5
#> name date date_year date_month date_day
```

```
#> <chr> <date> <dbl> <dbl> <int>
#> 1 Amy 2009-08-03 2009 8 3
#> 2 Bob 2010-01-16 2010 1 16
```

`across()` also makes it easy to supply multiple columns in a single argument because the first argument uses tidy-select; you just need to remember to embrace that argument, as we discussed in [Section 27.3.2](#). For example, this function will compute the means of numeric columns by default. But by supplying the second argument you can choose to summarize just selected columns:

```
summarize_means <- function(df, summary_vars = where(is.numeric))
 df |>
 summarize(
 across({{ summary_vars }}, \((x) mean(x, na.rm = TRUE),
 n = n())
)
 }
diamonds |>
 group_by(clarity) |>
 summarize_means()
#> # A tibble: 8 × 9
#> clarity carat depth table price x y z
#> <ord> <dbl> <dbl> <dbl> <dbl> <dbl> <dbl> <
#> 1 I1 1.28 62.7 58.3 3924. 6.76 6.71 4.21
#> 2 SI2 1.08 61.8 57.9 5063. 6.40 6.40 3.95
#> 3 SI1 0.850 61.9 57.7 3996. 5.89 5.89 3.64 1
#> 4 VS2 0.764 61.7 57.4 3925. 5.66 5.66 3.49 1
#> 5 VS1 0.727 61.7 57.3 3839. 5.57 5.58 3.44
#> 6 VVS2 0.596 61.7 57.0 3284. 5.22 5.23 3.22
#> # ... with 2 more rows

diamonds |>
 group_by(clarity) |>
 summarize_means(c(carat, x:z))
```

```
#> # A tibble: 8 × 6
#> clarity carat x y z n
#> <ord> <dbl> <dbl> <dbl> <dbl> <int>
#> 1 I1 1.28 6.76 6.71 4.21 741
#> 2 SI2 1.08 6.40 6.40 3.95 9194
#> 3 SI1 0.850 5.89 5.89 3.64 13065
#> 4 VS2 0.764 5.66 5.66 3.49 12258
#> 5 VS1 0.727 5.57 5.58 3.44 8171
#> 6 VVS2 0.596 5.22 5.23 3.22 5066
#> # ... with 2 more rows
```

## 28.2.7 Vs pivot\_longer()

Before we go on, it's worth pointing out an interesting connection between `across()` and `pivot_longer()` ([Section 6.3](#)). In many cases, you perform the same calculations by first pivoting the data and then performing the operations by group rather than by column. For example, take this multi-function summary:

```
df |>
 summarize(across(a:d, list(median = median, mean = mean)))
#> # A tibble: 1 × 8
#> a_median a_mean b_median b_mean c_median c_mean d_mean
#> <dbl> <dbl> <dbl> <dbl> <dbl> <dbl>
#> 1 0.0380 0.205 -0.0163 0.0910 0.260 0.0716
```

We could compute the same values by pivoting longer and then summarizing:

```
long <- df |>
 pivot_longer(a:d) |>
 group_by(name) |>
```

```
summarize(
 median = median(value),
 mean = mean(value)
)
long
#> # A tibble: 4 × 3
#> name median mean
#> <chr> <dbl> <dbl>
#> 1 a 0.0380 0.205
#> 2 b -0.0163 0.0910
#> 3 c 0.260 0.0716
#> 4 d 0.540 0.508
```

And if you wanted the same structure as `across()` you could pivot again:

```
long |>
pivot_wider(
 names_from = name,
 values_from = c(median, mean),
 names_vary = "slowest",
 names_glue = "{name}_{.value}"
)
#> # A tibble: 1 × 8
#> a_median a_mean b_median b_mean c_median c_mean d_mean
#> <dbl> <dbl> <dbl> <dbl> <dbl> <dbl>
#> 1 0.0380 0.205 -0.0163 0.0910 0.260 0.0716
```

This is a useful technique to know about because sometimes you'll hit a problem that's not currently possible to solve with `across()`: when you have groups of columns that you want to compute with simultaneously. For example, imagine that our data frame contains both values and weights and we want to compute a weighted mean:

```
df_paired <- tibble(
 a_val = rnorm(10),
 a_wts = runif(10),
 b_val = rnorm(10),
 b_wts = runif(10),
 c_val = rnorm(10),
 c_wts = runif(10),
 d_val = rnorm(10),
 d_wts = runif(10)
)
```

There's currently no way to do this with `across()`<sup>4</sup>, but it's relatively straightforward with `pivot_longer()`:

```
df_long <- df_paired |>
 pivot_longer(
 everything(),
 names_to = c("group", ".value"),
 names_sep = "_"
)

df_long
#> # A tibble: 40 × 3
#> group val wts
#> <chr> <dbl> <dbl>
#> 1 a 0.404 0.678
#> 2 b 1.74 0.650
#> 3 c -0.921 0.261
#> 4 d -0.953 0.327
#> 5 a 2.04 0.665
#> 6 b -1.64 0.815
#> # ... with 34 more rows

df_long |>
 group_by(group) |>
 summarize(mean = weighted.mean(val, wts))
```

```
#> # A tibble: 4 × 2
#> group mean
#> <chr> <dbl>
#> 1 a 0.109
#> 2 b 0.585
#> 3 c -0.746
#> 4 d -0.0142
```

If needed, you could `pivot_wider()` this back to the original form.

## 28.2.8 Exercises

1. Compute the number of unique values in each column of `palmerpenguins::penguins`.
2. Compute the mean of every column in `mtcars`.
3. Group `diamonds` by `cut`, `clarity`, and `color` then count the number of observations and the mean of each numeric column.
4. What happens if you use a list of functions, but don't name them? How is the output named?
5. It is possible to use `across()` inside `filter()` where it's equivalent to `if_all()`. Can you explain why?
6. Adjust `expand_dates()` to automatically remove the date columns after they've been expanded. Do you need to embrace any arguments?
7. Explain what each step of the pipeline in this function does. What special feature of `where()` are we taking advantage of?

```
show_missing <- function(df, group_vars, summary_var
 df |>
 group_by(pick({{ group_vars }})) |>
 summarize(
```

```
 across({{ summary_vars }}, \(\text{x}\) sum(is.na(\text{x})))
 .groups = "drop"
) |>
 select(where(\(\text{x}\) any(x > 0)))
}
nycflights13::flights |> show_missing(c(year, month,
```

## 28.3 Reading multiple files

In the previous section, you learned how to use `dplyr::across()` to repeat a transformation on multiple columns. In this section, you'll learn how to use `purrr::map()` to do something to every file in a directory. Let's start with a little motivation: imagine you have a directory full of excel spreadsheets<sup>5</sup> you want to read. You could do it with copy and paste:

```
data2019 <- readxl::read_excel("data/y2019.xlsx")
data2020 <- readxl::read_excel("data/y2020.xlsx")
data2021 <- readxl::read_excel("data/y2021.xlsx")
data2022 <- readxl::read_excel("data/y2022.xlsx")
```

And then use `dplyr::bind_rows()` to combine them all together:

```
data <- bind_rows(data2019, data2020, data2021, data2022)
```

You can imagine that this would get tedious quickly, especially if you had hundreds of files, not just four. The following sections show you how to automate this sort of task. There are three basic steps: use `list.files()` to list all the files in a directory, then use `purrr::map()` to read each of them into a list, then use

`purrr::list_rbind()` to combine them into a single data frame. We'll then discuss how you can handle situations of increasing heterogeneity, where you can't do exactly the same thing to every file.

### 28.3.1 Listing files in a directory

As the name suggests, `list.files()` lists the files in a directory. You'll almost always use three arguments:

- The first argument, `path`, is the directory to look in.
- `pattern` is a regular expression used to filter the file names. The most common pattern is something like `[.]xlsx$` or `[.]csv$` to find all files with a specified extension.
- `full.names` determines whether or not the directory name should be included in the output. You almost always want this to be `TRUE`.

To make our motivating example concrete, this book contains a folder with 12 excel spreadsheets containing data from the `gapminder` package. Each file contains one year's worth of data for 142 countries. We can list them all with the appropriate call to `list.files()`:

```
paths <- list.files("data/gapminder", pattern = "[.]xlsx"
paths
#> [1] "data/gapminder/1952.xlsx" "data/gapminder/1957.
#> [3] "data/gapminder/1962.xlsx" "data/gapminder/1967.
#> [5] "data/gapminder/1972.xlsx" "data/gapminder/1977.
#> [7] "data/gapminder/1982.xlsx" "data/gapminder/1987.
#> [9] "data/gapminder/1992.xlsx" "data/gapminder/1997.
#> [11] "data/gapminder/2002.xlsx" "data/gapminder/2007.
```

## 28.3.2 Lists

Now that we have these 12 paths, we could call `read_excel()` 12 times to get 12 data frames:

```
gapminder_1952 <- readxl::read_excel("data/gapminder/1952.xlsx")
gapminder_1957 <- readxl::read_excel("data/gapminder/1957.xlsx")
gapminder_1962 <- readxl::read_excel("data/gapminder/1962.xlsx")
...
gapminder_2007 <- readxl::read_excel("data/gapminder/2007.xlsx")
```

But putting each sheet into its own variable is going to make it hard to work with them a few steps down the road. Instead, they'll be easier to work with if we put them into a single object. A list is the perfect tool for this job:

```
files <- list(
 readxl::read_excel("data/gapminder/1952.xlsx"),
 readxl::read_excel("data/gapminder/1957.xlsx"),
 readxl::read_excel("data/gapminder/1962.xlsx"),
 ...,
 readxl::read_excel("data/gapminder/2007.xlsx")
)
```

Now that you have these data frames in a list, how do you get one out? You can use `files[[i]]` to extract the i-th element:

```
files[[3]]
#> # A tibble: 142 × 5
#> country continent lifeExp pop gdpPercap
#> <chr> <chr> <dbl> <dbl> <dbl>
#> 1 Afghanistan Asia 32.0 10267083 853.
```

```
#> 2 Albania Europe 64.8 1728137 2313.
#> 3 Algeria Africa 48.3 11000948 2551.
#> 4 Angola Africa 34 4826015 4269.
#> 5 Argentina Americas 65.1 21283783 7133.
#> 6 Australia Oceania 70.9 10794968 12217.
#> # ... with 136 more rows
```

We'll come back to `[[` in more detail in [Section 29.2](#).

### 28.3.3 `purrr::map()` and `list_rbind()`

The code to collect those data frames in a list “by hand” is basically just as tedious to type as code that reads the files one-by-one. Happily, we can use `purrr::map()` to make even better use of our `paths` vector. `map()` is similar to `across()`, but instead of doing something to each column in a data frame, it does something to each element of a vector. `map(x, f)` is shorthand for:

```
list(
 f(x[[1]]),
 f(x[[2]]),
 ...,
 f(x[[n]]))
```

So we can use `map()` get a list of 12 data frames:

```
files <- map(paths, readxl::read_excel)
length(files)
#> [1] 12

files[[1]]
#> # A tibble: 142 × 5
#> country continent lifeExp pop gdpPercap
#> <chr> <chr> <dbl> <dbl> <dbl>
#> 1 Afghanistan Asia 28.8 8425333 779.
```

```
#> 2 Albania Europe 55.2 1282697 1601.
#> 3 Algeria Africa 43.1 9279525 2449.
#> 4 Angola Africa 30.0 4232095 3521.
#> 5 Argentina Americas 62.5 17876956 5911.
#> 6 Australia Oceania 69.1 8691212 10040.
#> # ... with 136 more rows
```

(This is another data structure that doesn't display particularly compactly with `str()` so you might want to load it into RStudio and inspect it with `View()`).

Now we can use `purrr::list_rbind()` to combine that list of data frames into a single data frame:

```
list_rbind(files)
#> # A tibble: 1,704 × 5
#> country continent lifeExp pop gdpPercap
#> <chr> <chr> <dbl> <dbl> <dbl>
#> 1 Afghanistan Asia 28.8 8425333 779.
#> 2 Albania Europe 55.2 1282697 1601.
#> 3 Algeria Africa 43.1 9279525 2449.
#> 4 Angola Africa 30.0 4232095 3521.
#> 5 Argentina Americas 62.5 17876956 5911.
#> 6 Australia Oceania 69.1 8691212 10040.
#> # ... with 1,698 more rows
```

Or we could do both steps at once in a pipeline:

```
paths |>
 map(readxl::read_excel) |>
 list_rbind()
```

What if we want to pass in extra arguments to `read_excel()`? We use the same technique that we used with `across()`. For example, it's often useful to peek at the first few rows of the data with `n_max = 1`:

```
paths |>
 map(\(path) readxl::read_excel(path, n_max = 1)) |>
 list_rbind()
#> # A tibble: 12 × 5
#> country continent lifeExp pop gdpPercap
#> <chr> <chr> <dbl> <dbl> <dbl>
#> 1 Afghanistan Asia 28.8 8425333 779.
#> 2 Afghanistan Asia 30.3 9240934 821.
#> 3 Afghanistan Asia 32.0 10267083 853.
#> 4 Afghanistan Asia 34.0 11537966 836.
#> 5 Afghanistan Asia 36.1 13079460 740.
#> 6 Afghanistan Asia 38.4 14880372 786.
#> # ... with 6 more rows
```

This makes it clear that something is missing: there's no `year` column because that value is recorded in the path, not the individual files. We'll tackle that problem next.

#### 28.3.4 Data in the path

Sometimes the name of the file is data itself. In this example, the file name contains the year, which is not otherwise recorded in the individual files. To get that column into the final data frame, we need to do two things:

First, we name the vector of paths. The easiest way to do this is with the `set_names()` function, which can take a function. Here we use `basename()` to extract just the file name from the full path:

```
paths |> set_names(basename)
#> 1952.xlsx 1957.xlsx
#> "data/gapminder/1952.xlsx" "data/gapminder/1957.xlsx"
#> 1962.xlsx 1967.xlsx
#> "data/gapminder/1962.xlsx" "data/gapminder/1967.xlsx"
```

```
#> 1972.xlsx 1977.xlsx
#> "data/gapminder/1972.xlsx" "data/gapminder/1977.xlsx"
#> 1982.xlsx 1987.xlsx
#> "data/gapminder/1982.xlsx" "data/gapminder/1987.xlsx"
#> 1992.xlsx 1997.xlsx
#> "data/gapminder/1992.xlsx" "data/gapminder/1997.xlsx"
#> 2002.xlsx 2007.xlsx
#> "data/gapminder/2002.xlsx" "data/gapminder/2007.xlsx"
```

Those names are automatically carried along by all the map functions, so the list of data frames will have those same names:

```
files <- paths |>
 set_names(basename) |>
 map(readxl::read_excel)
```

That makes this call to `map()` shorthand for:

```
files <- list(
 "1952.xlsx" = readxl::read_excel("data/gapminder/1952",
 "1957.xlsx" = readxl::read_excel("data/gapminder/1957",
 "1962.xlsx" = readxl::read_excel("data/gapminder/1962",
 ...,
 "2007.xlsx" = readxl::read_excel("data/gapminder/2007.
)
```

You can also use `[ [` to extract elements by name:

```
files[["1962.xlsx"]]
#> # A tibble: 142 × 5
#> country continent lifeExp pop gdpPercap
#> <chr> <chr> <dbl> <dbl> <dbl>
#> 1 Afghanistan Asia 32.0 10267083 853.
```

```

#> 2 Albania Europe 64.8 1728137 2313.
#> 3 Algeria Africa 48.3 11000948 2551.
#> 4 Angola Africa 34 4826015 4269.
#> 5 Argentina Americas 65.1 21283783 7133.
#> 6 Australia Oceania 70.9 10794968 12217.
#> # ... with 136 more rows

```

Then we use the `names_to` argument to `list_rbind()` to tell it to save the names into a new column called `year` then use `readr::parse_number()` to extract the number from the string.

```

paths |>
 set_names(basename) |>
 map(readxl::read_excel) |>
 list_rbind(names_to = "year") |>
 mutate(year = parse_number(year))
#> # A tibble: 1,704 × 6
#> year country continent lifeExp pop gdpPer
#> <dbl> <chr> <chr> <dbl> <dbl> <dbl>
#> 1 1952 Afghanistan Asia 28.8 8425333 7
#> 2 1952 Albania Europe 55.2 1282697 16
#> 3 1952 Algeria Africa 43.1 9279525 24
#> 4 1952 Angola Africa 30.0 4232095 35
#> 5 1952 Argentina Americas 62.5 17876956 59
#> 6 1952 Australia Oceania 69.1 8691212 100
#> # ... with 1,698 more rows

```

In more complicated cases, there might be other variables stored in the directory name, or maybe the file name contains multiple bits of data. In that case, use `set_names()` (without any arguments) to record the full path, and then use `tidyverse::separate_wider_delim()` and friends to turn them into useful columns.

```
NOTE: this chapter also depends on dev tidyverse (in addition to dplyr)
paths |>
 set_names() |>
 map(readxl::read_excel) |>
 list_rbind(names_to = "year") |>
 separate_wider_delim(year, delim = "/", names = c(NA, "year")) |>
 separate_wider_delim(file, delim = ".", names = c("file", "ext"))
#> # A tibble: 1,704 × 8
#> dir file ext country continent lifeExp
#> <chr> <chr> <chr> <chr> <chr> <dbl>
#> 1 gapminder 1952 xlsx Afghanistan Asia 28.8
#> 2 gapminder 1952 xlsx Albania Europe 55.2
#> 3 gapminder 1952 xlsx Algeria Africa 43.1
#> 4 gapminder 1952 xlsx Angola Africa 30.6
#> 5 gapminder 1952 xlsx Argentina Americas 62.5
#> 6 gapminder 1952 xlsx Australia Oceania 69.1
#> # ... with 1,698 more rows
```

### 28.3.5 Save your work

Now that you've done all this hard work to get to a nice tidy data frame, it's a great time to save your work:

```
gapminder <- paths |>
 set_names(basename) |>
 map(readxl::read_excel) |>
 list_rbind(names_to = "year") |>
 mutate(year = parse_number(year))

write_csv(gapminder, "gapminder.csv")
```

Now when you come back to this problem in the future, you can read in a single csv file.

If you're working in a project, we'd suggest calling the file that does this sort of data prep work something like `0-cleanup.R`. The `0` in the file name suggests that this should be run before anything else.

If your input data files change over time, you might consider learning a tool like [targets](#) to set up your data cleaning code to automatically re-run whenever one of the input files is modified.

### 28.3.6 Many simple iterations

Here we've just loaded the data directly from disk, and were lucky enough to get a tidy dataset. In most cases, you'll need to do some additional tidying, and you have two basic options: you can do one round of iteration with a complex function, or do multiple rounds of iteration with simple functions. In our experience most folks reach first for one complex iteration, but you're often better by doing multiple simple iterations.

For example, imagine that you want to read in a bunch of files, filter out missing values, pivot, and then combine. One way to approach the problem is to write a function that takes a file and does all those steps then call `map()` once:

```
process_file <- function(path) {
 df <- read_csv(path)

 df |>
 filter(!is.na(id)) |>
 mutate(id = tolower(id)) |>
 pivot_longer(jan:dec, names_to = "month")
}

paths |>
```

```
map(process_file) |>
list_rbind()
```

Alternatively, you could perform each step of `process_file()` to every file:

```
paths |>
 map(read_csv) |>
 map(\df df |> filter(!is.na(id))) |>
 map(\df df |> mutate(id = tolower(id))) |>
 map(\df df |> pivot_longer(jan:dec, names_to = "mont
 list_rbind()
```

We recommend this approach because it stops you getting fixated on getting the first file right before moving on to the rest. By considering all of the data when doing tidying and cleaning, you're more likely to think holistically and end up with a higher quality result.

In this particular example, there's another optimization you could make, by binding all the data frames together earlier. Then you can rely on regular dplyr behavior:

```
paths |>
 map(read_csv) |>
 list_rbind() |>
 filter(!is.na(id)) |>
 mutate(id = tolower(id)) |>
 pivot_longer(jan:dec, names_to = "month")
```

### 28.3.7 Heterogeneous data

Unfortunately, sometimes it's not possible to go from `map()` straight to `list_rbind()` because the data frames are so heterogeneous that

`list_rbind()` either fails or yields a data frame that's not very useful. In that case, it's still useful to start by loading all of the files:

```
files <- paths |>
 map(readxl::read_excel)
```

Then a very useful strategy is to capture the structure of the data frames so that you can explore it using your data science skills. One way to do so is with this handy `df_types` function that returns a tibble with one row for each column:

```
df_types <- function(df) {
 tibble(
 col_name = names(df),
 col_type = map_chr(df, vctrs::vec_ptype_full),
 n_miss = map_int(df, \((x)) sum(is.na(x)))
)
}

df_types(starwars)
#> # A tibble: 14 × 3
#> col_name col_type n_miss
#> <chr> <chr> <int>
#> 1 name character 0
#> 2 height integer 6
#> 3 mass double 28
#> 4 hair_color character 5
#> 5 skin_color character 0
#> 6 eye_color character 0
#> # ... with 8 more rows
df_types(nycflights13::flights)
#> # A tibble: 19 × 3
#> col_name col_type n_miss
#> <chr> <chr> <int>
#> 1 year integer 0
```

```
#> 2 month integer 0
#> 3 day integer 0
#> 4 dep_time integer 8255
#> 5 sched_dep_time integer 0
#> 6 dep_delay double 8255
#> # ... with 13 more rows
```

You can then apply this function to all of the files, and maybe do some pivoting to make it easier to see where the differences are. For example, this makes it easy to verify that the gapminder spreadsheets that we've been working with are all quite homogeneous:

```
files |>
 map(df_types) |>
 list_rbind(names_to = "file_name") |>
 select(-n_miss) |>
 pivot_wider(names_from = col_name, values_from = col_t
#> # A tibble: 12 × 6
#> file_name country continent lifeExp pop gdpPer
#> <chr> <chr> <chr> <chr> <chr> <chr>
#> 1 1952.xlsx character character double double double
#> 2 1957.xlsx character character double double double
#> 3 1962.xlsx character character double double double
#> 4 1967.xlsx character character double double double
#> 5 1972.xlsx character character double double double
#> 6 1977.xlsx character character double double double
#> # ... with 6 more rows
```

If the files have heterogeneous formats, you might need to do more processing before you can successfully merge them. Unfortunately, we're now going to leave you to figure that out on your own, but you might want to read about `map_if()` and `map_at()`. `map_if()` allows you to selectively modify elements of a list based on their values;

`map_at()` allows you to selectively modify elements based on their names.

### 28.3.8 Handling failures

Sometimes the structure of your data might be sufficiently wild that you can't even read all the files with a single command. And then you'll encounter one of the downsides of map: it succeeds or fails as a whole.

`map()` will either successfully read all of the files in a directory or fail with an error, reading zero files. This is annoying: why does one failure prevent you from accessing all the other successes?

Luckily, purrr comes with a helper to tackle this problem: `possibly()`. `possibly()` is what's known as a function operator: it takes a function and returns a function with modified behavior. In particular, `possibly()` changes a function from erroring to returning a value that you specify:

```
files <- paths |>
 map(possibly(\(path) readxl::read_excel(path), NULL))

data <- files |> list_rbind()
```

This works particularly well here because `list_rbind()`, like many tidyverse functions, automatically ignores `NULL`s.

Now you have all the data that can be read easily, and it's time to tackle the hard part of figuring out why some files failed to load and what do to about it. Start by getting the paths that failed:

```
failed <- map_vec(files, is.null)
paths[failed]
#> character(0)
```

Then call the import function again for each failure and figure out what went wrong.

## 28.4 Saving multiple outputs

---

In the last section, you learned about `map()`, which is useful for reading multiple files into a single object. In this section, we'll now explore sort of the opposite problem: how can you take one or more R objects and save it to one or more files? We'll explore this challenge using three examples:

- Saving multiple data frames into one database.
- Saving multiple data frames into multiple `.csv` files.
- Saving multiple plots to multiple `.png` files.

### 28.4.1 Writing to a database

Sometimes when working with many files at once, it's not possible to fit all your data into memory at once, and you can't do `map(files, read_csv)`. One approach to deal with this problem is to load your data into a database so you can access just the bits you need with `dbplyr`.

If you're lucky, the database package you're using will provide a handy function that takes a vector of paths and loads them all into the database. This is the case with `duckdb`'s `duckdb_read_csv()`:

```
con <- DBI::dbConnect(duckdb::duckdb())
duckdb::duckdb_read_csv(con, "gapminder", paths)
```

This would work well here, but we don't have csv files, instead we have excel spreadsheets. So we're going to have to do it "by hand". Learning to do it by hand will also help you when you have a bunch of csvs and

the database that you're working with doesn't have one function that will load them all in.

We need to start by creating a table that will fill in with data. The easiest way to do this is by creating a template, a dummy data frame that contains all the columns we want, but only a sampling of the data. For the gapminder data, we can make that template by reading a single file and adding the year to it:

```
template <- readxl::read_excel(paths[[1]])
template$year <- 1952
template
#> # A tibble: 142 × 6
#> country continent lifeExp pop gdpPerCap y
#> <chr> <chr> <dbl> <dbl> <dbl> <c
#> 1 Afghanistan Asia 28.8 8425333 779. 1
#> 2 Albania Europe 55.2 1282697 1601. 1
#> 3 Algeria Africa 43.1 9279525 2449. 1
#> 4 Angola Africa 30.0 4232095 3521. 1
#> 5 Argentina Americas 62.5 17876956 5911. 1
#> 6 Australia Oceania 69.1 8691212 10040. 1
#> # ... with 136 more rows
```

Now we can connect to the database, and use `DBI::dbCreateTable()` to turn our template into a database table:

```
con <- DBI::dbConnect(duckdb::duckdb())
DBI::dbCreateTable(con, "gapminder", template)
```

`dbCreateTable()` doesn't use the data in `template`, just the variable names and types. So if we inspect the `gapminder` table now you'll see that it's empty but it has the variables we need with the types we expect:

```
con |> tbl("gapminder")
#> # Source: table<gapminder> [0 x 6]
#> # Database: DuckDB 0.6.2-dev1166 [unknown@Linux 5.15.
#> # ... with 6 variables: country <chr>, continent <chr>,
#> # pop <dbl>, gdpPercap <dbl>, year <dbl>
```

Next, we need a function that takes a single file path, reads it into R, and adds the result to the `gapminder` table. We can do that by combining `read_excel()` with `DBI::dbAppendTable()`:

```
append_file <- function(path) {
 df <- readxl::read_excel(path)
 df$year <- parse_number(basename(path))

 DBI::dbAppendTable(con, "gapminder", df)
}
```

Now we need to call `append_csv()` once for each element of `paths`. That's certainly possible with `map()`:

```
paths |> map(append_file)
```

But we don't care about the output of `append_file()`, so instead of `map()` it's slightly nicer to use `walk()`. `walk()` does exactly the same thing as `map()` but throws the output away:

```
paths |> walk(append_file)
```

Now we can see if we have all the data in our table:

```
con |>
 tbl("gapminder") |>
 count(year)

#> # Source: SQL [?? x 2]
#> # Database: DuckDB 0.6.2-dev1166 [unknown@Linux 5.15.
#> year n
#> <dbl> <dbl>
#> 1 1952 142
#> 2 1957 142
#> 3 1962 142
#> 4 1967 142
#> 5 1972 142
#> 6 1977 142
#> # ... with more rows
```

## 28.4.2 Writing csv files

The same basic principle applies if we want to write multiple csv files, one for each group. Let's imagine that we want to take the `ggplot2::diamonds` data and save one csv file for each `clarity`. First we need to make those individual datasets. There are many ways you could do that, but there's one way we particularly like: `group_nest()`.

```
by_clarity <- diamonds |>
 group_nest(clarity)

by_clarity
#> # A tibble: 8 × 2
#> clarity data
#> <ord> <list<tibble[,9]>>
#> 1 I1 [741 × 9]
#> 2 SI2 [9,194 × 9]
```

```
#> 3 SI1 [13,065 × 9]
#> 4 VS2 [12,258 × 9]
#> 5 VS1 [8,171 × 9]
#> 6 VVS2 [5,066 × 9]
#> # ... with 2 more rows
```

This gives us a new tibble with eight rows and two columns. `clarity` is our grouping variable and `data` is a list-column containing one tibble for each unique value of `clarity`:

```
by_clarity$data[[1]]
#> # A tibble: 741 × 9
#> carat cut color depth table price x y
#> <dbl> <ord> <ord> <dbl> <dbl> <int> <dbl> <dbl>
#> 1 0.32 Premium E 60.9 58 345 4.38 4.42
#> 2 1.17 Very Good J 60.2 61 2774 6.83 6.9
#> 3 1.01 Premium F 61.8 60 2781 6.39 6.36
#> 4 1.01 Fair E 64.5 58 2788 6.29 6.21
#> 5 0.96 Ideal F 60.7 55 2801 6.37 6.41
#> 6 1.04 Premium G 62.2 58 2801 6.46 6.41
#> # ... with 735 more rows
```

While we're here, let's create a column that gives the name of output file, using `mutate()` and `str_glue()`:

```
by_clarity <- by_clarity |>
 mutate(path = str_glue("diamonds-{clarity}.csv"))

by_clarity
#> # A tibble: 8 × 3
#> clarity data path
#> <ord> <list<tibble[,9]>> <glue>
#> 1 I1 [741 × 9] diamonds-I1.csv
#> 2 SI2 [9,194 × 9] diamonds-SI2.csv
#> 3 SI1 [13,065 × 9] diamonds-SI1.csv
```

```
#> 4 VS2 [12,258 × 9] diamonds-VS2.csv
#> 5 VS1 [8,171 × 9] diamonds-VS1.csv
#> 6 VVS2 [5,066 × 9] diamonds-VVS2.csv
#> # ... with 2 more rows
```

So if we were going to save these data frames by hand, we might write something like:

```
write_csv(by_clarity$data[[1]], by_clarity$path[[1]])
write_csv(by_clarity$data[[2]], by_clarity$path[[2]])
write_csv(by_clarity$data[[3]], by_clarity$path[[3]])
...
write_csv(by_clarity$by_clarity[[8]], by_clarity$path[[8]])
```

This is a little different to our previous uses of `map()` because there are two arguments that are changing, not just one. That means we need a new function: `map2()`, which varies both the first and second arguments. And because we again don't care about the output, we want `walk2()` rather than `map2()`. That gives us:

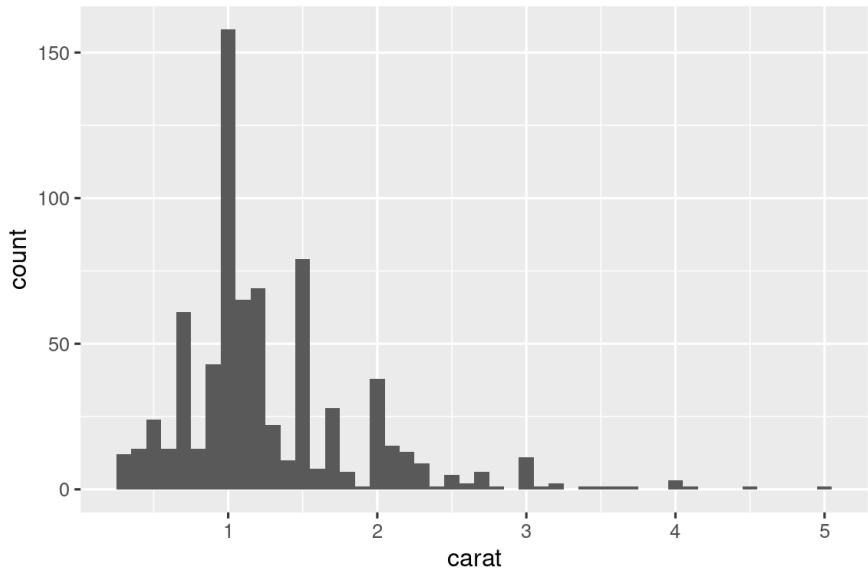

```
walk2(by_clarity$data, by_clarity$path, write_csv)
```

### 28.4.3 Saving plots

We can take the same basic approach to create many plots. Let's first make a function that draws the plot we want:

```
carat_histogram <- function(df) {
 ggplot(df, aes(x = carat)) + geom_histogram(binwidth = 1)
}

carat_histogram(by_clarity$data[[1]])
```

Now we can use `map()` to create a list of many plots<sup>6</sup> and their eventual file paths:

```
by_clarity <- by_clarity |>
 mutate(
 plot = map(data, carat_histogram),
 path = str_glue("clarity-{clarity}.png")
)
```

Then use `walk2()` with `ggsave()` to save each plot:

```
walk2(
 by_clarity$path,
 by_clarity$plot,
 \path, plot) ggsave(path, plot, width = 6, height = 6
)
```

This is shorthand for:

```
ggsave(by_clarity$path[[1]], by_clarity$plot[[1]], width
ggsave(by_clarity$path[[2]], by_clarity$plot[[2]], width
ggsave(by_clarity$path[[3]], by_clarity$plot[[3]], width
...
ggsave(by_clarity$path[[8]], by_clarity$plot[[8]], width
```

## 28.5 Summary

---

In this chapter, you've seen how to use explicit iteration to solve three problems that come up frequently when doing data science: manipulating multiple columns, reading multiple files, and saving multiple outputs. But in general, iteration is a super power: if you know the right iteration technique, you can easily go from fixing one problem to fixing all the problems. Once you've mastered the techniques in this chapter, we highly recommend learning more by reading the [Functionals chapter](#) of *Advanced R* and consulting the [purrr website](#).

If you know much about iteration in other languages, you might be surprised that we didn't discuss the `for` loop. That's because R's orientation towards data analysis changes how we iterate: in most cases you can rely on an existing idiom to do something to each column or each group. And when you can't, you can often use a functional programming tool like `map()` that does something to each element of a list. However, you will see `for` loops in wild-caught code, so you'll learn about them in the next chapter where we'll discuss some important base R tools.

---

1. Anonymous, because we never explicitly gave it a name with `<-`. Another term programmers use for this is “lambda function”.

2. In older code you might see syntax that looks like `~ .x + 1`. This is another way to write anonymous functions but it only works inside tidyverse functions and always uses the variable name `.x`. We now recommend the base syntax, `\(x) x + 1`. 
3. You can't currently change the order of the columns, but you could reorder them after the fact using `relocate()` or similar. 
4. Maybe there will be one day, but currently we don't see how. 
5. If you instead had a directory of csv files with the same format, you can use the technique from [Section 8.4.](#) 
6. You can print `by_clarity$plot` to get a crude animation — you'll get one plot for each element of `plots`. NOTE: this didn't happen for me. 

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

## 29 A field guide to base R

>

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

To finish off the programming section, we’re going to give you a quick tour of the most important base R functions that we don’t otherwise discuss in the book. These tools are particularly useful as you do more programming and will help you read code that you’ll encounter in the wild.

This is a good place to remind you that the tidyverse is not the only way to solve data science problems. We teach the tidyverse in this book because tidyverse packages share a common design philosophy, which increases the consistency across functions, making each new function or package a little easier to learn and use. It’s not possible to use the tidyverse without using base R, so we’ve actually already taught you a **lot** of base R functions: from `library()` to load packages, to `sum()` and `mean()` for numeric summaries, to the factor, date, and POSIXct data types, and of course all the basic operators like `+`, `-`, `/`, `*`, `|`, `&`, and `!`. What we haven’t focused on so far is base R workflows, so we will highlight a few of those in this chapter.

After you read this book you’ll learn other approaches to the same problems using base R, `data.table`, and other packages. You’ll certainly encounter these other approaches when you start reading R code written by other people, particularly if you’re using StackOverflow. It’s

100% okay to write code that uses a mix of approaches, and don't let anyone tell you otherwise!

In this chapter, we'll focus on four big topics: subsetting with `[`, subsetting with `[[` and `$`, the `apply` family of functions, and `for` loops. To finish off, we'll briefly discuss two important plotting functions.

## 29.0.1 Prerequisites

```
library(tidyverse)
```

# 29.1 Selecting multiple elements with `[`

`[` is used to extract sub-components from vectors and data frames, and is called like `x[i]` or `x[i, j]`. In this section, we'll introduce you to the power of `[`, first showing you how you can use it with vectors, then how the same principles extend in a straightforward way to two-dimensional (2d) structures like data frames. We'll then help you cement that knowledge by showing how various dplyr verbs are special cases of `[`.

## 29.1.1 Subsetting vectors

There are five main types of things that you can subset a vector with, i.e. that can be the `i` in `x[i]`:

1. **A vector of positive integers.** Subsetting with positive integers keeps the elements at those positions:

```
x <- c("one", "two", "three", "four", "five")
x[c(3, 2, 5)]
```

```
#> [1] "three" "two" "five"
```

By repeating a position, you can actually make a longer output than input, making the term “subsetting” a bit of a misnomer.

```
x[c(1, 1, 5, 5, 5, 2)]
#> [1] "one" "one" "five" "five" "five" "two"
```

2. **A vector of negative integers.** Negative values drop the elements at the specified positions:

```
x[c(-1, -3, -5)]
#> [1] "two" "four"
```

3. **A logical vector.** Subsetting with a logical vector keeps all values corresponding to a TRUE value. This is most often useful in conjunction with the comparison functions.

```
x <- c(10, 3, NA, 5, 8, 1, NA)

All non-missing values of x
x[!is.na(x)]
#> [1] 10 3 5 8 1

All even (or missing!) values of x
x[x %% 2 == 0]
#> [1] 10 NA 8 NA
```

Note that, unlike `filter()`, NA indices will be included in the output as NAs.

4. **A character vector.** If you have a named vector, you can subset it with a character vector:

```
x <- c(abc = 1, def = 2, xyz = 5)
x[c("xyz", "def")]
```

```
#> xyz def
#> 5 2
```

As with subsetting with positive integers, you can use a character vector to duplicate individual entries.

5. **Nothing**. The final type of subsetting is nothing, `x []`, which returns the complete `x`. This is not useful for subsetting vectors, but as we'll see shortly it is useful when subsetting 2d structures like tibbles.

### 29.1.2 Subsetting data frames

There are quite a few different ways<sup>1</sup> that you can use `[` with a data frame, but the most important way is to select rows and columns independently with `df[rows, cols]`. Here `rows` and `cols` are vectors as described above. For example, `df[rows, ]` and `df[, cols]` select just rows or just columns, using the empty subset to preserve the other dimension.

Here are a couple of examples:

```
df <- tibble(
 x = 1:3,
 y = c("a", "e", "f"),
 z = runif(3)
)

Select first row and second column
df[1, 2]
#> # A tibble: 1 × 1
#> y
#> <chr>
#> 1 a

Select all rows and columns x and y
df[, c("x", "y")]
```

```
#> # A tibble: 3 × 2
#> x y
#> <int> <chr>
#> 1 1 a
#> 2 2 e
#> 3 3 f

Select rows where `x` is greater than 1 and all columns
df[df$x > 1,]
#> # A tibble: 2 × 3
#> x y z
#> <int> <chr> <dbl>
#> 1 2 e 0.834
#> 2 3 f 0.601
```

We'll come back to `$` shortly, but you should be able to guess what `df$x` does from the context: it extracts the `x` variable from `df`. We need to use it here because `[` doesn't use tidy evaluation, so you need to be explicit about the source of the `x` variable.

There's an important difference between tibbles and data frames when it comes to `[`. In this book we've mostly used tibbles, which *are* data frames, but they tweak some older behaviors to make your life a little easier. In most places, you can use "tibble" and "data frame" interchangeably, so when we want to draw particular attention to R's built-in data frame, we'll write `data.frame`. If `df` is a `data.frame`, then `df[, cols]` will return a vector if `col` selects a single column and a data frame if it selects more than one column. If `df` is a tibble, then `[` will always return a tibble.

```
df1 <- data.frame(x = 1:3)
df1[, "x"]
#> [1] 1 2 3
```

```
df2 <- tibble(x = 1:3)
df2[, "x"]
#> # A tibble: 3 × 1
#> x
#> <int>
#> 1 1
#> 2 2
#> 3 3
```

One way to avoid this ambiguity with `data.frames` is to explicitly specify `drop = FALSE`:

```
df1[, "x" , drop = FALSE]
#> x
#> 1 1
#> 2 2
#> 3 3
```

### 29.1.3 dplyr equivalents

A number of dplyr verbs are special cases of `[ :`

- `filter()` is equivalent to subsetting the rows with a logical vector, taking care to exclude missing values:

```
df <- tibble(
 x = c(2, 3, 1, 1, NA),
 y = letters[1:5],
 z = runif(5)
)
df |> filter(x > 1)

same as
df[!is.na(df$x) & df$x > 1,]
```

Another common technique in the wild is to use `which()` for its side-effect of dropping missing values: `df[which(df$x > 1), ]`.

- `arrange()` is equivalent to subsetting the rows with an integer vector, usually created with `order()`:

```
df |> arrange(x, y)

same as
df[order(dfx, dfy),]
```

You can use `order(decreasing = TRUE)` to sort all columns in descending order or `-rank(col)` to individually sort columns in decreasing order.

- Both `select()` and `relocate()` are similar to subsetting the columns with a character vector:

```
df |> select(x, z)

same as
df[, c("x", "z")]
```

Base R also provides a function that combines the features of `filter()` and `select()`<sup>2</sup> called `subset()`:

```
df |>
 filter(x > 1) |>
 select(y, z)
#> # A tibble: 2 × 2
#> y z
#> <chr> <dbl>
#> 1 a 0.157
#> 2 b 0.00740
```

```
same as
df |> subset(x > 1, c(y, z))
#> # A tibble: 2 × 2
#> y z
#> <chr> <dbl>
#> 1 a 0.157
#> 2 b 0.00740
```

This function was the inspiration for much of dplyr's syntax.

## 29.1.4 Exercises

1. Create functions that take a vector as input and return:
  - a. The elements at even numbered positions.
  - b. Every element except the last value.
  - c. Only even values (and no missing values).
2. Why is `x[-which(x > 0)]` not the same as `x[x <= 0]`? Read the documentation for `which()` and do some experiments to figure it out.

## 29.2 Selecting a single element \$ and [[

---

`[`, which selects many elements, is paired with `[[` and `$`, which extract a single element. In this section, we'll show you how to use `[[` and `$` to pull columns out of data frames, discuss a couple more differences between `data.frames` and tibbles, and emphasize some important differences between `[` and `[[` when used with lists.

### 29.2.1 Data frames

`[[` and `$` can be used to extract columns out of a data frame. `[[` can access by position or by name, and `$` is specialized for access by name:

```
tb <- tibble(
 x = 1:4,
 y = c(10, 4, 1, 21)
)

by position
tb[[1]]
#> [1] 1 2 3 4

by name
tb[["x"]]
#> [1] 1 2 3 4
tb$x
#> [1] 1 2 3 4
```

They can also be used to create new columns, the base R equivalent of `mutate()`:

```
tb$z <- tb$x + tb$y
tb
#> # A tibble: 4 × 3
#> x y z
#> <int> <dbl> <dbl>
#> 1 1 10 11
#> 2 2 4 6
#> 3 3 1 4
#> 4 4 21 25
```

There are a number of other base R approaches to creating new columns including with `transform()`, `with()`, and `within()`. Hadley collected a few examples at

<https://gist.github.com/hadley/1986a273e384fb2d4d752c18ed71bedf>.

Using `$` directly is convenient when performing quick summaries. For example, if you just want to find the size of the biggest diamond or the possible values of `cut`, there's no need to use `summarize()`:

```
max(diamonds$carat)
#> [1] 5.01

levels(diamonds$cut)
#> [1] "Fair" "Good" "Very Good" "Premium" "
```

dplyr also provides an equivalent to `[[ / $` that we didn't mention in [Chapter 4](#): `pull()`. `pull()` takes either a variable name or variable position and returns just that column. That means we could rewrite the above code to use the pipe:

```
diamonds |> pull(carat) |> mean()
#> [1] 0.7979397

diamonds |> pull(cut) |> levels()
#> [1] "Fair" "Good" "Very Good" "Premium" "
```

## 29.2.2 Tibbles

There are a couple of important differences between tibbles and base `data.frames` when it comes to `$`. Data frames match the prefix of any variable names (so-called **partial matching**) and don't complain if a column doesn't exist:

```
df <- data.frame(x1 = 1)
df$x
#> [1] 1
```

```
df$z
#> NULL
```

Tibbles are more strict: they only ever match variable names exactly and they will generate a warning if the column you are trying to access doesn't exist:

```
tb <- tibble(x1 = 1)

tb$x
#> Warning: Unknown or uninitialised column: `x`.
#> NULL
tb$z
#> Warning: Unknown or uninitialised column: `z`.
#> NULL
```

For this reason we sometimes joke that tibbles are lazy and surly: they do less and complain more.

### 29.2.3 Lists

[ [ and \$ are also really important for working with lists, and it's important to understand how they differ from [ . Lets illustrate the differences with a list named l :

```
l <- list(
 a = 1:3,
 b = "a string",
 c = pi,
 d = list(-1, -5)
)
```

- [ extracts a sub-list. It doesn't matter how many elements you extract, the result will always be a list.

```
str(l[1:2])
#> List of 2
#> $ a: int [1:3] 1 2 3
#> $ b: chr "a string"
str(l[1])
#> List of 1
#> $ a: int [1:3] 1 2 3
str(l[4])
#> List of 1
#> $ d:List of 2
#> ..$: num -1
#> ..$: num -5
```

Like with vectors, you can subset with a logical, integer, or character vector.

- `[]` and `$` extract a single component from a list. They remove a level of hierarchy from the list.

```
str(l[[1]])
#> int [1:3] 1 2 3
str(l[[4]])
#> List of 2
#> $: num -1
#> $: num -5

str(l$a)
#> int [1:3] 1 2 3
```

The difference between `[` and `[[` is particularly important for lists because `[[` drills down into the list while `[` returns a new, smaller list. To help you remember the difference, take a look at the an unusual pepper shaker shown in [Figure 29.1](#). If this pepper shaker is your list `pepper`, then, `pepper[1]` is a pepper shaker containing a single pepper packet, as in [Figure 29.2](#). If we suppose this pepper shaker is a

list pepper , then, pepper [1] is a pepper shaker containing a single pepper packet, as in [Figure 29.2](#). pepper [2] would look the same, but would contain the second packet. pepper [1:2] would be a pepper shaker containing two pepper packets. pepper [[1]] would extract the pepper packet itself, as in [Figure 29.3](#).

 A photo of a glass pepper shaker. Instead of the pepper shaker containing pepper, it contains many packets of pepper.

Figure 29.1: A pepper shaker that Hadley once found in his hotel room.

 A photo of the glass pepper shaker containing just one packet of pepper.

Figure 29.2: pepper [1]

 A photo of single packet of pepper.

Figure 29.3: pepper [[1]]

This same principle applies when you use 1d [ with a data frame:

```
df <- tibble(x = 1:3, y = 3:5)

returns a one-column data frame
df[["x"]]
#> # A tibble: 3 × 1
#> x
#> <int>
#> 1 1
#> 2 2
#> 3 3

returns the contents of x
df[["x"]]
#> [1] 1 2 3
```

## 29.2.4 Exercises

1. What happens when you use `[[]` with a positive integer that's bigger than the length of the vector? What happens when you subset with a name that doesn't exist?
2. What would `pepper[[1]][1]` be? What about `pepper[[1]][[1]]`?

## 29.3 Apply family

---

In [Chapter 28](#), you learned tidyverse techniques for iteration like `dplyr::across()` and the `map` family of functions. In this section, you'll learn about their base equivalents, the **apply family**. In this context `apply` and `map` are synonyms because another way of saying “map a function over each element of a vector” is “apply a function over each element of a vector”. Here we'll give you a quick overview of this family so you can recognize them in the wild.

The most important member of this family is `lapply()`, which is very similar to `purrr::map()`<sup>3</sup>. In fact, because we haven't used any of `map()`'s more advanced features, you can replace every `map()` call in [Chapter 28](#) with `lapply()`.

There's no exact base R equivalent to `across()` but you can get close by using `[` with `lapply()`. This works because under the hood, data frames are lists of columns, so calling `lapply()` on a data frame applies the function to each column.

```
df <- tibble(a = 1, b = 2, c = "a", d = "b", e = 4)

First find numeric columns
```

```
num_cols <- sapply(df, is.numeric)
num_cols
#> a b c d e
#> TRUE TRUE FALSE FALSE TRUE

Then transform each column with lapply() then replace
df[, num_cols] <- lapply(df[, num_cols, drop = FALSE], \
df
#> # A tibble: 1 × 5
#> a b c d e
#> <dbl> <dbl> <chr> <chr> <dbl>
#> 1 2 4 a b 8
```

The code above uses a new function, `sapply()`. It's similar to `lapply()` but it always tries to simplify the result, hence the `s` in its name, here producing a logical vector instead of a list. We don't recommend using it for programming, because the simplification can fail and give you an unexpected type, but it's usually fine for interactive use. `purrr` has a similar function called `map_vec()` that we didn't mention in [Chapter 28](#).

Base R provides a stricter version of `sapply()` called `vapply()`, short for `vector apply`. It takes an additional argument that specifies the expected type, ensuring that simplification occurs the same way regardless of the input. For example, we could replace the `sapply()` call above with this `vapply()` where we specify that we expect `is.numeric()` to return a logical vector of length 1:

```
vapply(df, is.numeric, logical(1))
#> a b c d e
#> TRUE TRUE FALSE FALSE TRUE
```

The distinction between `sapply()` and `vapply()` is really important when they're inside a function (because it makes a big difference to the

function's robustness to unusual inputs), but it doesn't usually matter in data analysis.

Another important member of the apply family is `tapply()` which computes a single grouped summary:

```
diamonds |>
 group_by(cut) |>
 summarize(price = mean(price))
#> # A tibble: 5 × 2
#> cut price
#> <ord> <dbl>
#> 1 Fair 4359.
#> 2 Good 3929.
#> 3 Very Good 3982.
#> 4 Premium 4584.
#> 5 Ideal 3458.

tapply(diamonds$price, diamonds$cut, mean)
#> Fair Good Very Good Premium Ideal
#> 4358.758 3928.864 3981.760 4584.258 3457.542
```

Unfortunately `tapply()` returns its results in a named vector which requires some gymnastics if you want to collect multiple summaries and grouping variables into a data frame (it's certainly possible to not do this and just work with free floating vectors, but in our experience that just delays the work). If you want to see how you might use `tapply()` or other base techniques to perform other grouped summaries, Hadley has collected a few techniques [in a gist](#).

The final member of the apply family is the titular `apply()`, which works with matrices and arrays. In particular, watch out for `apply(df, 2, something)`, which is a slow and potentially dangerous way of doing `lapply(df, something)`. This rarely comes up in data science because we usually work with data frames and not matrices.

## 29.4 For loops

---

`for` loops are the fundamental building block of iteration that both the apply and map families use under the hood. `for` loops are powerful and general tools that are important to learn as you become a more experienced R programmer. The basic structure of a `for` loop looks like this:

```
for (element in vector) {
 # do something with element
}
```

The most straightforward use of `for` loops is to achieve the same effect as `walk()`: call some function with a side-effect on each element of a list. For example, in [Section 28.4.1](#) instead of using `walk`:

```
paths |> walk	append_file)
```

We could have used a `for` loop:

```
for (path in paths) {
 append_file(path)
}
```

Things get a little trickier if you want to save the output of the `for` loop, for example reading all of the excel files in a directory like we did in [Chapter 28](#):

```
paths <- dir("data/gapminder", pattern = "\\.xlsx$", full
files <- map(paths, readxl::read_excel)
```

There are a few different techniques that you can use, but we recommend being explicit about what the output is going to look like upfront. In this case, we're going to want a list the same length as `paths`, which we can create with `vector()`:

```
files <- vector("list", length(paths))
```

Then instead of iterating over the elements of `paths`, we'll iterate over their indices, using `seq_along()` to generate one index for each element of `paths`:

```
seq_along(paths)
#> [1] 1 2 3 4 5 6 7 8 9 10 11 12
```

Using the indices is important because it allows us to link to each position in the input with the corresponding position in the output:

```
for (i in seq_along(paths)) {
 files[[i]] <- readxl::read_excel(paths[[i]])
}
```

To combine the list of tibbles into a single tibble you can use `do.call() + rbind()`:

```
do.call(rbind, files)
#> # A tibble: 1,704 × 5
#> country continent lifeExp pop gdpPercap
#> <chr> <chr> <dbl> <dbl> <dbl>
#> 1 Afghanistan Asia 28.8 8425333 779.
#> 2 Albania Europe 55.2 1282697 1601.
#> 3 Algeria Africa 43.1 9279525 2449.
#> 4 Angola Africa 30.0 4232095 3521.
#> 5 Argentina Americas 62.5 17876956 5911.
```

```
#> 6 Australia Oceania 69.1 8691212 10040.
#> # ... with 1,698 more rows
```

Rather than making a list and saving the results as we go, a simpler approach is to build up the data frame piece-by-piece:

```
out <- NULL
for (path in paths) {
 out <- rbind(out, readxl::read_excel(path))
}
```

We recommend avoiding this pattern because it can become very slow when the vector is very long. This is the source of the persistent canard that `for` loops are slow: they're not, but iteratively growing a vector is.

## 29.5 Plots

---

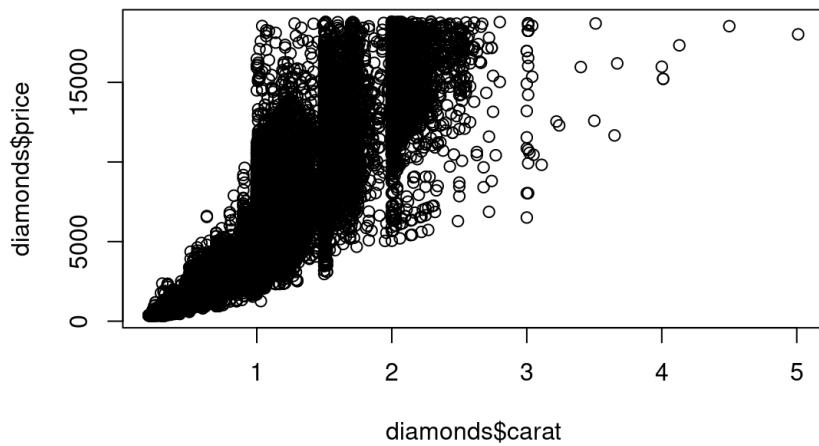

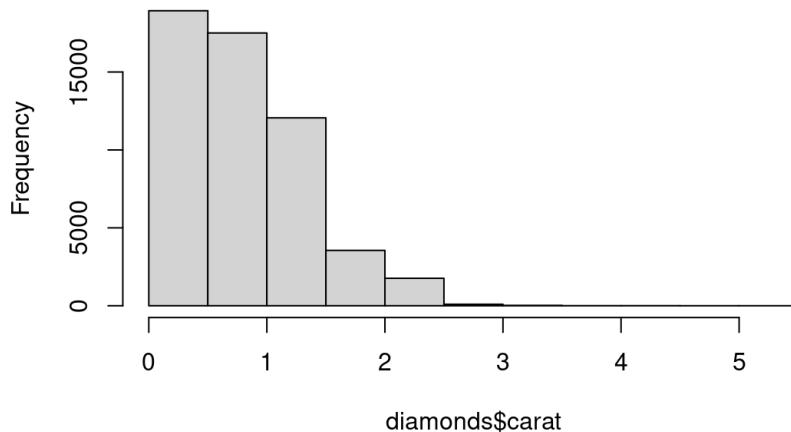

Many R users who don't otherwise use the tidyverse prefer ggplot2 for plotting due to helpful features like sensible defaults, automatic legends, and a modern look. However, base R plotting functions can still be useful because they're so concise — it takes very little typing to do a basic exploratory plot.

There are two main types of base plot you'll see in the wild: scatterplots and histograms, produced with `plot()` and `hist()` respectively. Here's a quick example from the diamonds dataset:

```
hist(diamonds$carat)

plot(diamonds$carat, diamonds$price)
```

### Histogram of diamonds\$carat

Note that base plotting functions work with vectors, so you need to pull columns out of the data frame using `$` or some other technique.

## 29.6 Summary

---

In this chapter, we've shown you a selection of base R functions useful for subsetting and iteration. Compared to approaches discussed elsewhere in the book, these functions tend to have more of a "vector" flavor than a "data frame" flavor because base R functions tend to take individual vectors, rather than a data frame and some column specification. This often makes life easier for programming and so becomes more important as you write more functions and begin to write your own packages.

This chapter concludes the programming section of the book. You've made a solid start on your journey to becoming not just a data scientist who uses R, but a data scientist who can *program* in R. We hope these chapters have sparked your interest in programming and that you're looking forward to learning more outside of this book.

---

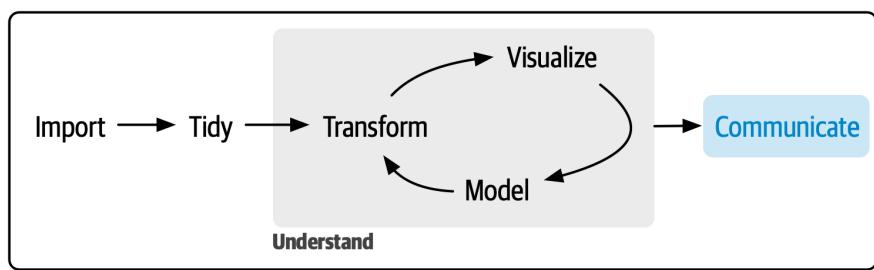

1. Read <https://adv-r.hadley.nz/subsetting.html#subset-multiple> to see how you can also subset a data frame like it is a 1d object and how you can subset it with a matrix. 
2. But it doesn't handle grouped data frames differently and it doesn't support selection helper functions like `starts_with()`. 
3. It just lacks convenient features like progress bars and reporting which element caused the problem if there's an error. 

# Communicate

>

So far, you've learned the tools to get your data into R, tidy it into a form convenient for analysis, and then understand your data through transformation, and visualization. However, it doesn't matter how great your analysis is unless you can explain it to others: you need to **communicate** your results.

Program

Figure 1: Communication is the final part of the data science process; if you can't communicate your results to other humans, it doesn't matter how great your analysis is.

Communication is the theme of the following three chapters:

- In [Chapter 30](#), you will learn about Quarto, a tool for integrating prose, code, and results. You can use Quarto for analyst-to-analyst communication as well as analyst-to-decision-maker communication. Thanks to the power of Quarto formats, you can even use the same document for both purposes.
- In [Chapter 31](#), you'll learn a little about the many other varieties of outputs you can produce using Quarto, including dashboards, websites, and books.

- We'll finish up with [Chapter 32](#), where you'll learn about the “analysis notebook” and how to systematically record your successes and failures so that you can learn from them.

These chapters focus mostly on the technical mechanics of communication, not the really hard problems of communicating your thoughts to other humans. However, there are lot of other great books about communication, which we'll point you to at the end of each chapter.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

## 30.1 Introduction

Quarto provides a unified authoring framework for data science, combining your code, its results, and your prose. Quarto documents are fully reproducible and support dozens of output formats, like PDFs, Word files, presentations, and more.

Quarto files are designed to be used in three ways:

1. For communicating to decision makers, who want to focus on the conclusions, not the code behind the analysis.
2. For collaborating with other data scientists (including future you!), who are interested in both your conclusions, and how you reached them (i.e. the code).
3. As an environment in which to *do* data science, as a modern day lab notebook where you can capture not only what you did, but also what you were thinking.

Quarto is a command line interface tool, not an R package. This means that help is, by-and-large, not available through ?. Instead, as you work through this chapter, and use Quarto in the future, you should refer to the Quarto documentation page at <https://quarto.org> for help.

If you're an R Markdown user, you might be thinking "Quarto sounds a lot like R Markdown". You're not wrong! Quarto unifies the functionality of many packages from the R Markdown ecosystem (rmarkdown, bookdown, distill, xaringan, etc.) into a single consistent system as well as extends it with native support for multiple programming languages like Python and Julia in addition to R. In a way, Quarto reflects everything that was learned from expanding and supporting the R Markdown ecosystem over a decade.

### 30.1.1 Prerequisites

You need the Quarto command line interface (Quarto CLI), but you don't need to explicitly install it or load it, as RStudio automatically does both when needed.

## 30.2 Quarto basics

---

This is a Quarto file – a plain text file that has the extension `.qmd`:

```

```

```
title: "Diamond sizes"
date: 2022-09-12
format: html

```{r}
#| label: setup
#| include: false  
  
library(tidyverse)  
  
smaller <- diamonds |>
  filter(carat <= 2.5)
...``
```

We have data about `r nrow(diamonds)` diamonds.
Only `r nrow(diamonds) - nrow(smaller)` are larger than 2.5 carats.

The distribution of the remainder is shown below:

```
```{r}
#| label: plot-smaller-diamonds
#| echo: false

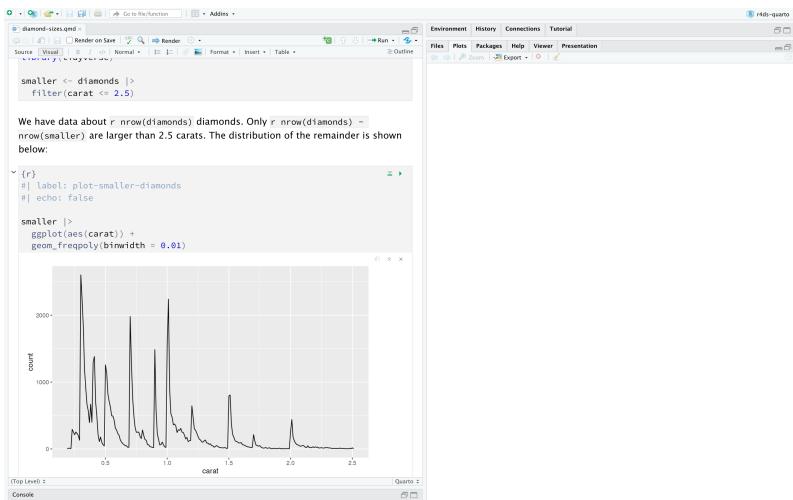

smaller |>
 ggplot(aes(x = carat)) +
 geom_freqpoly(binwidth = 0.01)
```

```

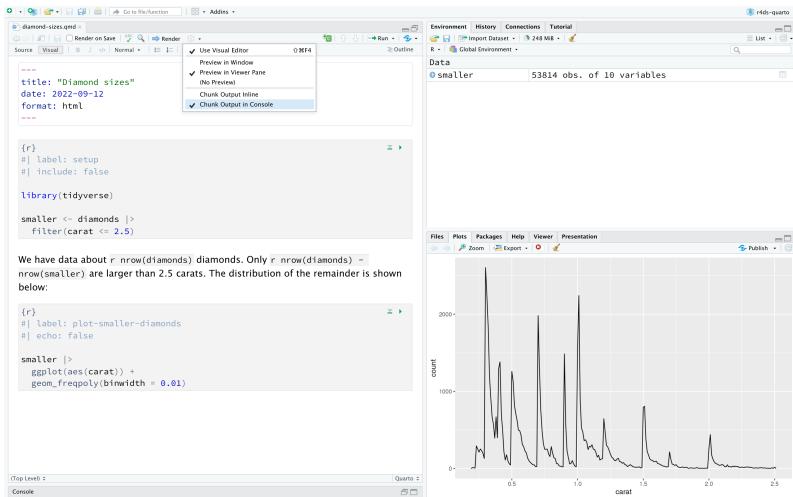

It contains three important types of content:

1. An (optional) **YAML header** surrounded by --- s.
2. **Chunks** of R code surrounded by ``` .
3. Text mixed with simple text formatting like # heading and _italics_.

When you open a .qmd , you get a notebook interface where code and output are interleaved. You can run each code chunk by clicking the Run icon (it looks like a play button at the top of the chunk), or by pressing Cmd/Ctrl + Shift + Enter. RStudio executes the code and displays the results inline with the code:

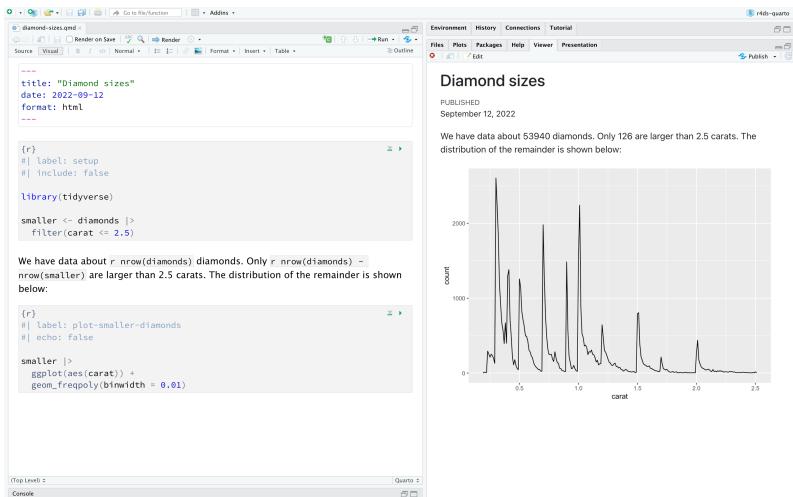

If you don't like seeing your plots and output in your document and would rather make use of RStudio's console and plot panes, you can click on the gear icon next to "Render" and switch to "Chunk Output in Console".

To produce a complete report containing all text, code, and results, click "Render" or press Cmd/Ctrl + Shift + K. You can also do this programmatically with `quarto::quarto_render("diamond-`

`sizes.qmd")` . This will display the report in the viewer pane and create an HTML file.

When you render the document, Quarto sends the `.qmd` file to **knitr**, <https://yihui.name/knitr>, which executes all of the code chunks and creates a new markdown (`.md`) document which includes the code and its output. The markdown file generated by knitr is then processed by **pandoc**, <https://pandoc.org>, which is responsible for creating the finished file. The advantage of this two step workflow is that you can create a very wide range of output formats, as you'll learn about in [Chapter 31](#).

To get started with your own `.qmd` file, select *File > New File > Quarto Document...* in the menu bar. RStudio will launch a wizard that you can use to pre-populate your file with useful content that reminds you how the key features of Quarto work.

The following sections dive into the three components of a Quarto document in more details: the markdown text, the code chunks, and the YAML header.

30.2.1 Exercises

1. Create a new Quarto document using *File > New File > Quarto Document*. Read the instructions. Practice running the chunks individually. Then render the document by clicking the appropriate button and then by using the appropriate keyboard short cut. Verify that you can modify the code, re-run it, and see modified output.
2. Create one new Quarto document for each of the three built-in formats: HTML, PDF and Word. Render each of the three documents. How do the outputs differ? How do the inputs differ? (You may need to install LaTeX in order to build the PDF output — RStudio will prompt you if this is necessary.)

30.3 Visual editor

The Visual editor in RStudio provides a WYSIWYM interface for authoring Quarto documents. Under the hood, prose in Quarto documents (`.qmd` files) is written in Markdown, a lightweight set of conventions for formatting plain text files. In fact, Quarto uses Pandoc markdown (a slightly extended version of Markdown that Quarto understands), including tables, citations, cross-references, footnotes, divs/spans, definition lists, attributes, raw HTML/TeX, and more as well as support for executing code cells and viewing their output inline. While Markdown is designed to be easy to read and write, as you will see in [Section 30.4](#), it still requires learning new syntax. Therefore, if you're new to computational documents like `.qmd` files but have experience

using tools like Google Docs or MS Word, the easiest way to get started with Quarto in RStudio is the visual editor.

In the visual editor you can either use the buttons on the menu bar to insert images, tables, cross-references, etc. or you can use the catch-all `⌘ /` shortcut to insert just about anything. If you are at the beginning of a line (as shown below), you can also enter just `/` to invoke the shortcut.

The screenshot shows the RStudio visual editor interface with the following content:

- Text formatting**: A toolbar with icons for italic, bold, underline, strikethrough, small caps, code, superscript², and subscript₂.
- Headings**: A section containing **1st Level Header**, **2nd Level Header**, and **3rd Level Header**.
- Lists**: A bulleted list:
 - Bulleted list item 1
 - Item 2
 - Item 2a
 - Item 2b
- Numbered lists**:
 1. Numbered list item 1
 2. Item 2. The numbers are incremented automatically in the output.
- Links and images**: A section with a link to <http://example.com> and a link phrase [linked phrase](http://example.com). Below these are two examples of links:
 - <http://example.com> (with a preview icon)
 - A preview of the Quarto logo with the word "quarto" below it.
- Figure dialog**: A modal dialog titled "Figure" with tabs for **Image**, **Attributes**, and **Advanced**.
 - Image (File or URL):** A text input field containing "quarto.png" with a "Browse..." button.
 - Width:** 320, **Height:** 77, **px**, **Lock ratio** checked.
 - Alignment:** Default (radio button selected), Left, Center, Right.
 - Caption:** optional caption text (empty).
 - Alternative text:** Quarto logo and the word quarto spelled in small case letters (empty).
 - Link to:** (empty).
- Table structure**: A table with three rows and two columns.

| First Header | Second Header |
|--------------|---------------|
| Content Cell | Content Cell |
| Content Cell | Content Cell |
- Code completion dropdown**: A list of suggestions:
 - R Code Chunk
 - Executable R chunk
 - Python Code Chunk
 - Executable Python chunk
 - Div...
 - Block containing other con...
 - Bullet List
 - List using bullets for items
 - Numbered List
 - List using numbers for items
 - Heading 1
 - Part heading

Inserting images and customizing how they are displayed is also facilitated with the visual editor. You can either paste an image from your clipboard directly into the visual editor (and RStudio will place a copy of that image in the project directory and link to it) or you can use the visual editor's Insert > Figure / Image menu to browse to the image

you want to insert or paste its URL. In addition, using the same menu you can resize the image as well as add a caption, alternative text, and a link.

The visual editor has many more features that we haven't enumerated here that you might find useful as you gain experience authoring with it.

Most importantly, while the visual editor displays your content with formatting, under the hood, it saves your content in plain Markdown and you can switch back and forth between the visual and source editors to view and edit your content using either tool.

30.3.1 Exercises

30.4 Source editor

You can also edit Quarto documents using the Source editor in RStudio, without the assist of the Visual editor. While the Visual editor will feel familiar to those with experience writing in tools like Google docs, the Source editor will feel familiar to those with experience writing R scripts or R Markdown documents. The Source editor can also be useful for debugging any Quarto syntax errors since it's often easier to catch these in plain text.

The guide below shows how to use Pandoc's Markdown for authoring Quarto documents in the source editor.

```
## Text formatting

*italic* **bold** [underline]{.underline} ~~strikeout~~
[small caps]{.smallcaps} `code` superscript^2^ and
subscript~2~
```

```
## Headings

# 1st Level Header

## 2nd Level Header

#### 3rd Level Header

## Lists
```

- Bulleted list item 1
- Item 2
 - Item 2a
 - Item 2b

1. Numbered list item 1
2. Item 2.

The numbers are incremented automatically in the output.

```
## Links and images

| Content Cell | Content Cell |
| Content Cell | Content Cell |

/

The best way to learn these is simply to try them out. It will take a few days, but soon they will become second nature, and you won't need to think about them. If you forget, you can get to a handy reference sheet with *Help > Markdown Quick Reference*.

30.4.1 Exercises

1. Practice what you've learned by creating a brief CV. The title should be your name, and you should include headings for (at least) education or employment. Each of the sections should include a bulleted list of jobs/degrees. Highlight the year in bold.
2. Using the visual editor, figure out how to:
 - a. Add a footnote.
 - b. Add a horizontal rule.
 - c. Add a block quote.
3. Now, using the source editor and the Markdown quick reference, figure out how to:
 - a. Add a footnote.
 - b. Add a horizontal rule.
 - c. Add a block quote.
4. Copy and paste the contents of `diamond-sizes.qmd` from <https://github.com/hadley/r4ds/tree/main/quarto> in to a local R Quarto document. Check that you can run it, then add text after the frequency polygon that describes its most striking features.

30.5 Code chunks

To run code inside a Quarto document, you need to insert a chunk.

There are three ways to do so:

1. The keyboard shortcut Cmd + Option + I / Ctrl + Alt + I.
2. The “Insert” button icon in the editor toolbar.
3. By manually typing the chunk delimiters ````{r}` and `````.

We’d recommend you learn the keyboard shortcut. It will save you a lot of time in the long run!

You can continue to run the code using the keyboard shortcut that by now (we hope!) you know and love: Cmd/Ctrl + Enter. However, chunks get a new keyboard shortcut: Cmd/Ctrl + Shift + Enter, which runs all the code in the chunk. Think of a chunk like a function. A chunk should be relatively self-contained, and focused around a single task.

The following sections describe the chunk header which consists of ````{r}`, followed by an optional chunk label and various other chunk options, each on their own line, marked by `#|`.

30.5.1 Chunk label

Chunks can be given an optional label, e.g.

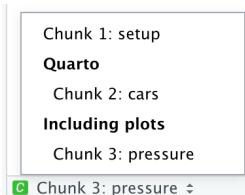

```
```{r}
#| label: simple-addition
```

```
1 + 1
```
```

```
#> [1] 2
```

This has three advantages:

1. You can more easily navigate to specific chunks using the drop-down code navigator in the bottom-left of the script editor:

2. Graphics produced by the chunks will have useful names that make them easier to use elsewhere. More on that in [Section 30.6](#).
3. You can set up networks of cached chunks to avoid re-performing expensive computations on every run. More on that in [Section 30.8](#).

Your chunk labels should be short but evocative and should not contain spaces. We recommend using dashes (–) to separate words (instead of underscores, _) and avoiding other special characters in chunk labels.

You are generally free to label your chunk however you like, but there is one chunk name that imbues special behavior: `setup`. When you're in a notebook mode, the chunk named `setup` will be run automatically once, before any other code is run.

Additionally, chunk labels cannot be duplicated. Each chunk label must be unique.

30.5.2 Chunk options

Chunk output can be customized with **options**, fields supplied to chunk header. Knitr provides almost 60 options that you can use to customize your code chunks. Here we'll cover the most important chunk options

that you'll use frequently. You can see the full list at

<https://yihui.name/knitr/options>.

The most important set of options controls if your code block is executed and what results are inserted in the finished report:

- `eval: false` prevents code from being evaluated. (And obviously if the code is not run, no results will be generated). This is useful for displaying example code, or for disabling a large block of code without commenting each line.
- `include: false` runs the code, but doesn't show the code or results in the final document. Use this for setup code that you don't want cluttering your report.
- `echo: false` prevents code, but not the results from appearing in the finished file. Use this when writing reports aimed at people who don't want to see the underlying R code.
- `message: false` or `warning: false` prevents messages or warnings from appearing in the finished file.
- `results: hide` hides printed output; `fig-show: hide` hides plots.
- `error: true` causes the render to continue even if code returns an error. This is rarely something you'll want to include in the final version of your report, but can be very useful if you need to debug exactly what is going on inside your `.qmd`. It's also useful if you're teaching R and want to deliberately include an error. The default, `error: false` causes rendering to fail if there is a single error in the document.

Each of these chunk options get added to the header of the chunk, following `#|`, e.g. in the following chunk the result is not printed since

`eval` is set to false.

```
```{r}
#| label: simple-multiplication
#| eval: false

2 * 2
```

```

The following table summarizes which types of output each option suppresses:

| Option | Run | Show | | | | |
|---|------|------|--------|-------|----------|----------|
| | code | code | Output | Plots | Messages | Warnings |
| <code>eval:</code>
false | - | - | - | - | - | - |
| <code>include:</code>
false | - | - | - | - | - | - |
| <code>echo:</code>
false | - | - | - | - | - | - |
| <code>results:</code>
hide | - | - | - | - | - | - |
| <code>fig-</code>
<code>show:</code>
hide | - | - | - | - | - | - |
| <code>message:</code>
false | - | - | - | - | - | - |

| Option | Run | Show | code | code | Output | Plots | Messages | Warnings |
|----------|------|------|------|------|--------|-------|----------|----------|
| | code | code | | | | | | |
| warning: | | - | | | | | | |
| false | | | | | | | | |

30.5.3 Global options

As you work more with knitr, you will discover that some of the default chunk options don't fit your needs and you want to change them.

You can do this by adding the preferred options in the document YAML, under `execute`. For example, if you are preparing a report for an audience who does not need to see your code but only your results and narrative, you might set `echo: false` at the document level. That will hide the code by default, so only showing the chunks you deliberately choose to show (with `echo: true`). You might consider setting `message: false` and `warning: false`, but that would make it harder to debug problems because you wouldn't see any messages in the final document.

```
title: "My report"  
execute:  
  echo: false
```

Since Quarto is designed to be multi-lingual (works with R as well as other languages like Python, Julia, etc.), all of the knitr options are not available at the document execution level since some of them only work with knitr and not other engines Quarto uses for running code in other languages (e.g. Jupyter). You can, however, still set these as global options for your document under the `knitr` field, under `opts_chunk`. For example, when writing books and tutorials we set:

```
title: "Tutorial"  
knitr:  
  opts_chunk:  
    comment: "#>"  
    collapse: true
```

This uses our preferred comment formatting and ensures that the code and output are kept closely entwined.

30.5.4 Inline code

There is one other way to embed R code into a Quarto document: directly into the text, with: `r`. This can be very useful if you mention properties of your data in the text. For example, the example document used at the start of the chapter had:

We have data about `r nrow(diamonds)` diamonds. Only `r nrow(diamonds) - nrow(smaller)` are larger than 2.5 carats. The distribution of the remainder is shown below:

When the report is rendered, the results of these computations are inserted into the text:

We have data about 53940 diamonds. Only 126 are larger than 2.5 carats. The distribution of the remainder is shown below:

When inserting numbers into text, `format()` is your friend. It allows you to set the number of digits so you don't print to a ridiculous degree of accuracy, and a `big.mark` to make numbers easier to read. You might combine these into a helper function:

```
comma <- function(x) format(x, digits = 2, big.mark = ",")  
comma(3452345)
```

```
#> [1] "3,452,345"  
comma(.12358124331)  
#> [1] "0.12"
```

30.5.5 Exercises

1. Add a section that explores how diamond sizes vary by cut, color, and clarity. Assume you're writing a report for someone who doesn't know R, and instead of setting `echo: false` on each chunk, set a global option.
2. Download `diamond-sizes.qmd` from <https://github.com/hadley/r4ds/tree/main/quarto>. Add a section that describes the largest 20 diamonds, including a table that displays their most important attributes.
3. Modify `diamonds-sizes.qmd` to use `label_comma()` to produce nicely formatted output. Also include the percentage of diamonds that are larger than 2.5 carats.

30.6 Figures

The figures in a Quarto document can be embedded (e.g. a PNG or JPEG file) or generated as a result of a code chunk.

To embed an image from an external file, you can use the Insert menu in RStudio and select Figure / Image. This will pop open a menu where you can browse to the image you want to insert as well as add alternative text or caption to it and adjust its size. In the visual editor you can also simply paste an image from your clipboard into your document and RStudio will place a copy of that image in your project folder.

If you include a code chunk that generates a figure (e.g. includes a `ggplot()` call), the resulting figure will be automatically included in your Quarto document.

30.6.1 Figure sizing

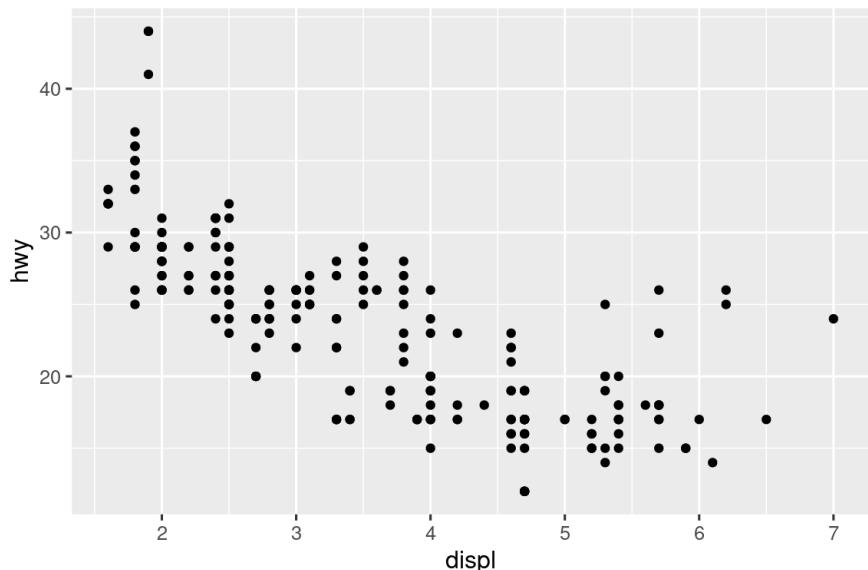

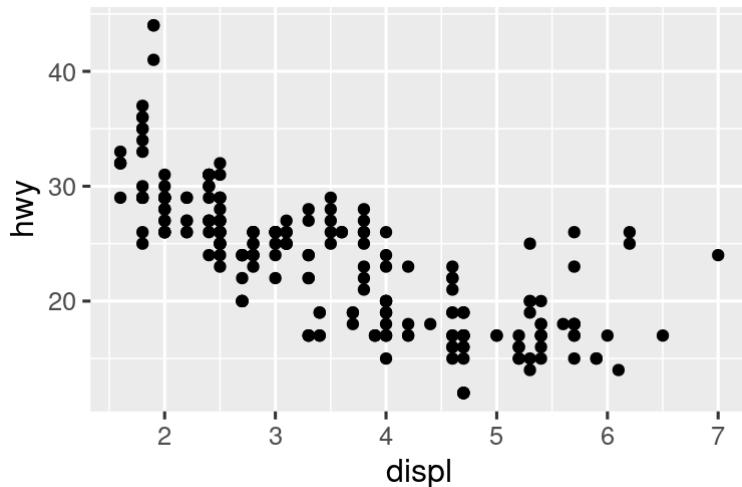

The biggest challenge of graphics in Quarto is getting your figures the right size and shape. There are five main options that control figure sizing: `fig-width`, `fig-height`, `fig-aspect`, `out-width` and `out-height`. Image sizing is challenging because there are two sizes (the size of the figure created by R and the size at which it is inserted in the output document), and multiple ways of specifying the size (i.e. height, width, and aspect ratio: pick two of three).

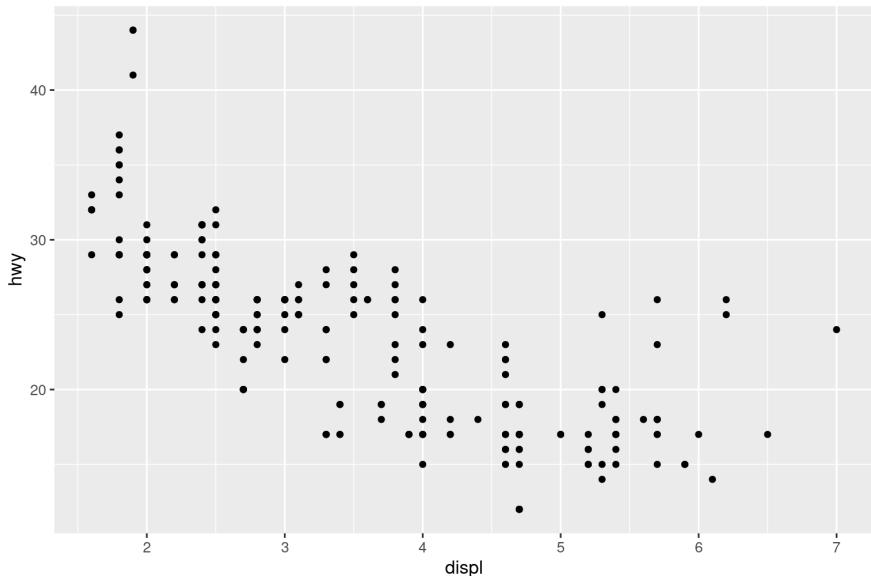

We recommend three of the five options:

- Plots tend to be more aesthetically pleasing if they have consistent width. To enforce this, set `fig-width: 6` (6") and `fig-aspect: 0.618` (the golden ratio) in the defaults. Then in individual chunks, only adjust `fig-aspect`.
- Control the output size with `out-width` and set it to a percentage of the line width. We suggest to `out-width: "70%"` and `fig-align: "center"`. That gives plots room to breathe, without taking up too much space.
- To put multiple plots in a single row, set the `out-width` to `50%` for two plots, `33%` for 3 plots, or `25%` to 4 plots, and set `fig-align: "default"`. Depending on what you're trying to illustrate (e.g. show data or show plot variations), you might also tweak `fig-width`, as discussed below.

If you find that you're having to squint to read the text in your plot, you need to tweak `fig-width`. If `fig-width` is larger than the size the

figure is rendered in the final doc, the text will be too small; if `fig-width` is smaller, the text will be too big. You'll often need to do a little experimentation to figure out the right ratio between the `fig-width` and the eventual width in your document. To illustrate the principle, the following three plots have `fig-width` of 4, 6, and 8 respectively:

If you want to make sure the font size is consistent across all your figures, whenever you set `out-width`, you'll also need to adjust `fig-width` to maintain the same ratio with your default `out-width`. For example, if your default `fig-width` is 6 and `out-width` is 0.7, when you set `out-width: "50%"` you'll need to set `fig-width` to 4.3 ($6 * 0.5 / 0.7$).

30.6.2 Other important options

When mingling code and text, like in this book, you can set `fig-show: "hold"` so that plots are shown after the code. This has the pleasant side effect of forcing you to break up large blocks of code with their explanations.

To add a caption to the plot, use `fig-cap`. In Quarto this will change the figure from inline to “floating”.

If you're producing PDF output, the default graphics type is PDF. This is a good default because PDFs are high quality vector graphics. However,

they can produce very large and slow plots if you are displaying thousands of points. In that case, set `fig-format: "png"` to force the use of PNGs. They are slightly lower quality, but will be much more compact.

It's a good idea to name code chunks that produce figures, even if you don't routinely label other chunks. The chunk label is used to generate the file name of the graphic on disk, so naming your chunks makes it much easier to pick out plots and reuse in other circumstances (i.e. if you want to quickly drop a single plot into an email or a tweet).

30.6.3 Exercises

30.7 Tables

Similar to figures, you can include two types of tables in a Quarto document. They can be markdown tables that you create directly in your Quarto document (using the Insert Table menu) or they can be tables generated as a result of a code chunk. In this section we will focus on the latter, tables generated via computation.

By default, Quarto prints data frames and matrices as you'd see them in the console:

```
mtcars[1:5, ]  
#>          mpg cyl disp  hp drat    wt  qsec  
#> Mazda RX4     21.0   6 160 110 3.90 2.620 16.46  
#> Mazda RX4 Wag 21.0   6 160 110 3.90 2.875 17.02  
#> Datsun 710    22.8   4 108  93 3.85 2.320 18.61  
#> Hornet 4 Drive 21.4   6 258 110 3.08 3.215 19.44  
#> Hornet Sportabout 18.7   8 360 175 3.15 3.440 17.02
```

If you prefer that data be displayed with additional formatting you can use the `knitr::kable()` function. The code below generates [Table 30.1](#).

```
knitr::kable(mtcars[1:5, ], )
```

Table 30.1: A knitr kable.

| | mpg | cyl | disp | hp | drat | wt | qsec | vs | am | gear | carb |
|-------------------|------|-----|------|-----|------|-------|-------|----|----|------|------|
| Mazda RX4 | 21.0 | 6 | 160 | 110 | 3.90 | 2.620 | 16.46 | 0 | 1 | 4 | 4 |
| Mazda RX4 Wag | 21.0 | 6 | 160 | 110 | 3.90 | 2.875 | 17.02 | 0 | 1 | 4 | 4 |
| Datsun 710 | 22.8 | 4 | 108 | 93 | 3.85 | 2.320 | 18.61 | 1 | 1 | 4 | 1 |
| Hornet 4 Drive | 21.4 | 6 | 258 | 110 | 3.08 | 3.215 | 19.44 | 1 | 0 | 3 | 1 |
| Hornet Sportabout | 18.7 | 8 | 360 | 175 | 3.15 | 3.440 | 17.02 | 0 | 0 | 3 | 2 |

Read the documentation for `?knitr::kable` to see the other ways in which you can customize the table. For even deeper customization, consider the **gt**, **huxtable**, **reactable**, **kableExtra**, **xtable**, **stargazer**, **pander**, **tables**, and **ascii** packages. Each provides a set of tools for returning formatted tables from R code.

There is also a rich set of options for controlling how figures are embedded. You'll learn about these in [?sec-graphics-communication](#).

30.7.1 Exercises

30.8 Caching

Normally, each render of a document starts from a completely clean slate. This is great for reproducibility, because it ensures that you've captured every important computation in code. However, it can be painful if you have some computations that take a long time. The solution is `cache: true`.

You can enable the Knitr cache at the document level for caching the results of all computations in a document using standard YAML options:

```
---
```

```
title: "My Document"
execute:
  cache: true
---
```

You can also enable caching at the chunk level for caching the results of computation in a specific chunk:

```
```{r}
#| cache: true

code for lengthy computation...
```

```

When set, this will save the output of the chunk to a specially named file on disk. On subsequent runs, knitr will check to see if the code has changed, and if it hasn't, it will reuse the cached results.

The caching system must be used with care, because by default it is based on the code only, not its dependencies. For example, here the

`processed_data` chunk depends on the `raw-data` chunk:

```
```{r}
#| label: raw-data

rawdata <- readr::read_csv("a_very_large_file.csv")
```

```{r}
#| label: processed-data
#| cache: true

processed_data <- rawdata |>
 filter(!is.na(import_var)) |>
 mutate(new_variable = complicated_transformation(x, y,
z))
```

```

Caching the `processed_data` chunk means that it will get re-run if the `dplyr` pipeline is changed, but it won't get rerun if the `read_csv()` call changes. You can avoid that problem with the `dependson` chunk option:

```
```{r}
#| label: processed-data
#| cache: true
#| dependson: "raw-data"

processed_data <- rawdata |>
 filter(!is.na(import_var)) |>
 mutate(new_variable = complicated_transformation(x, y,
z))
```

```

`dependson` should contain a character vector of *every* chunk that the cached chunk depends on. Knitr will update the results for the cached

chunk whenever it detects that one of its dependencies have changed.

Note that the chunks won't update if `a_very_large_file.csv` changes, because knitr caching only tracks changes within the `.qmd` file. If you want to also track changes to that file you can use the `cache.extra` option. This is an arbitrary R expression that will invalidate the cache whenever it changes. A good function to use is `file.info()`: it returns a bunch of information about the file including when it was last modified. Then you can write:

```
```{r}
#| label: raw-data
#| cache.extra: file.info("a_very_large_file.csv")

rawdata <- readr::read_csv("a_very_large_file.csv")
```

```

As your caching strategies get progressively more complicated, it's a good idea to regularly clear out all your caches with `knitr::clean_cache()`.

We've followed the advice of [David Robinson](#) to name these chunks: each chunk is named after the primary object that it creates. This makes it easier to understand the `dependson` specification.

30.8.1 Exercises

1. Set up a network of chunks where `d` depends on `c` and `b`, and both `b` and `c` depend on `a`. Have each chunk print `lubridate::now()`, set `cache: true`, then verify your understanding of caching.

7ff2b1502187f15a978d74f59a88534fa6f1012e

Troubleshooting

Troubleshooting Quarto documents can be challenging because you are no longer in an interactive R environment, and you will need to learn some new tricks. Additionally, the error could be due to issues with the Quarto document itself or due to the R code in the Quarto document.

One common error in documents with code chunks is duplicated chunk labels, which are especially pervasive if your workflow involves copying and pasting code chunks. To address this issue, all you need to do is to change one of your duplicated labels.

If the errors are due to the R code in the document, the first thing you should always try is to recreate the problem in an interactive session. Restart R, then “Run all chunks” (either from Code menu, under Run region), or with the keyboard shortcut Ctrl + Alt + R. If you’re lucky, that will recreate the problem, and you can figure out what’s going on interactively.

If that doesn’t help, there must be something different between your interactive environment and the Quarto environment. You’re going to need to systematically explore the options. The most common difference is the working directory: the working directory of a Quarto is the directory in which it lives. Check the working directory is what you expect by including `getwd()` in a chunk.

Next, brainstorm all the things that might cause the bug. You’ll need to systematically check that they’re the same in your R session and your Quarto session. The easiest way to do that is to set `error: true` on the chunk causing the problem, then use `print()` and `str()` to check that settings are as you expect.

30.9 YAML header

You can control many other “whole document” settings by tweaking the parameters of the YAML header. You might wonder what YAML stands for: it’s “YAML Ain’t Markup Language”, which is designed for representing hierarchical data in a way that’s easy for humans to read and write. Quarto uses it to control many details of the output. Here we’ll discuss three: self-contained documents, document parameters, and bibliographies.

30.9.1 Self-contained

HTML documents typically have a number of external dependencies (e.g. images, CSS style sheets, JavaScript, etc.) and, by default, Quarto places these dependencies in a `_files` folder in the same directory as your `.qmd` file. If you publish the HTML file on a hosting platform (e.g. QuartoPub, <https://quartopub.com/>), the dependencies in this directory are published with your document and hence are available in the published report. However, if you want to email the report to a colleague, you might prefer to have a single, self-contained, HTML document that embeds all of its dependencies. You can do this by specifying the `embed-resources` option:

By default these dependencies are placed in a `_files` directory alongside your document. For example, if you render `report.qmd` to HTML:

```
format:  
  html:  
    embed-resources: true
```

The resulting file will be self-contained, such that it will need no external files and no internet access to be displayed properly by a browser.

30.9.2 Parameters

Quarto documents can include one or more parameters whose values can be set when you render the report. Parameters are useful when you want to re-render the same report with distinct values for various key inputs. For example, you might be producing sales reports per branch, exam results by student, or demographic summaries by country. To declare one or more parameters, use the `params` field.

This example uses a `my_class` parameter to determine which class of cars to display:

```
---
```

```
output: html_document
params:
  my_class: "suv"
---  
  
```{r}
#| label: setup
#| include: false

library(tidyverse)

class <- mpg |> filter(class == params$my_class)
```
  
  
# Fuel economy for `r params$my_class`'s
```

```
```{r}
#| message: false

ggplot(class, aes(x = displ, y = hwy)) +
 geom_point() +
 geom_smooth(se = FALSE)
```

```

As you can see, parameters are available within the code chunks as a read-only list named `params`.

You can write atomic vectors directly into the YAML header. You can also run arbitrary R expressions by prefacing the parameter value with `!r`. This is a good way to specify date/time parameters.

```
params:
  start: !r lubridate::ymd("2015-01-01")
  snapshot: !r lubridate::ymd_hms("2015-01-01 12:30:00")
```

30.9.3 Bibliographies and Citations

Quarto can automatically generate citations and a bibliography in a number of styles. The most straightforward way of adding citations and bibliographies to a Quarto document is using the visual editor in RStudio.

To add a citation using the visual editor, go to Insert > Citation. Citations can be inserted from a variety of sources:

1. [DOI](#) (Document Object Identifier) references.
2. [Zotero](#) personal or group libraries.
3. Searches of [Crossref](#), [DataCite](#), or [PubMed](#).

4. Your document bibliography (a `.bib` file in the directory of your document)

Under the hood, the visual mode uses the standard Pandoc markdown representation for citations (e.g. `[@citation]`).

If you add a citation using one of the first three methods, the visual editor will automatically create a `bibliography.bib` file for you and add the reference to it. It will also add a `bibliography` field to the document YAML. As you add more references, this file will get populated with their citations. You can also directly edit this file using many common bibliography formats including BibLaTeX, BibTeX, EndNote, Medline.

To create a citation within your `.qmd` file in the source editor, use a key composed of '@' + the citation identifier from the bibliography file. Then place the citation in square brackets. Here are some examples:

Separate multiple citations with a `;`:
Blah blah [`@smith04`]; Blah blah [`@doe99`].

You can add arbitrary comments inside the square bracket
Blah blah [see `@doe99`, pp. 33–35; also `@smith04`, ch. 1].

Remove the square brackets to create an in-text citation
says blah, or `@smith04` [p. 33] says blah.

Add a `-' before the citation to suppress the author's name
Smith says blah [-`@smith04`].

When Quarto renders your file, it will build and append a bibliography to the end of your document. The bibliography will contain each of the cited references from your bibliography file, but it will not contain a section heading. As a result it is common practice to end your file with a

section header for the bibliography, such as `# References` or `# Bibliography`.

You can change the style of your citations and bibliography by referencing a CSL (citation style language) file in the `csl` field:

```
bibliography: rmarkdown.bib  
csl: apa.csl
```

As with the bibliography field, your csl file should contain a path to the file. Here we assume that the csl file is in the same directory as the .qmd file. A good place to find CSL style files for common bibliography styles is <https://github.com/citation-style-language/styles>.

30.10 Learning more

Quarto is still relatively young, and is still growing rapidly. The best place to stay on top of innovations is the official Quarto website:
<https://quarto.org>.

There are two important topics that we haven't covered here: collaboration and the details of accurately communicating your ideas to other humans. Collaboration is a vital part of modern data science, and you can make your life much easier by using version control tools, like Git and GitHub. We recommend "Happy Git with R", a user friendly introduction to Git and GitHub from R users, by Jenny Bryan. The book is freely available online: <https://happygitwithr.com>.

We have also not touched on what you should actually write in order to clearly communicate the results of your analysis. To improve your writing, we highly recommend reading either *Style: Lessons in Clarity and Grace* by Joseph M. Williams & Joseph Bizup, or *The Sense of Structure: Writing from the Reader's Perspective* by George Gopen. Both

books will help you understand the structure of sentences and paragraphs, and give you the tools to make your writing more clear. (These books are rather expensive if purchased new, but they're used by many English classes so there are plenty of cheap second-hand copies). George Gopen also has a number of short articles on writing at <https://www.georgegopen.com/the-litigation-articles.html>. They are aimed at lawyers, but almost everything applies to data scientists too.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).

ⓘ You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

31.1 Introduction

So far, you've seen Quarto used to produce HTML documents. This chapter gives a brief overview of some of the many other types of output you can produce with Quarto.

There are two ways to set the output of a document:

1. Permanently, by modifying the YAML header:

```
title: "Diamond sizes"
format: html
```

2. Transiently, by calling `quarto::quarto_render()` by hand:

```
quarto::quarto_render("diamond-sizes.qmd", output_format = "docx")
```

This is useful if you want to programmatically produce multiple types of output since the `output_format` argument can also take a list of values.

```
quarto::quarto_render("diamond-sizes.qmd", output_format = c("docx", "pdf"))
```

31.2 Output options

Quarto offers a wide range of output formats. You can find the complete list at <https://quarto.org/docs/output-formats/all-formats.html>. Many formats share some output options (e.g., `toc: true` for including a table of contents), but others have options that are format specific (e.g., `code-fold: true` collapses code chunks into a `<details>` tag for HTML output so the user can display it on demand, it's not applicable in a PDF or Word document).

To override the default options, you need to use an expanded `format` field. For example, if you wanted to render an `html` with a floating table of contents, you'd use:

```
format:
  html:
    toc: true
    toc_float: true
```

You can even render to multiple outputs by supplying a list of formats:

```
format:
  html:
```

```
toc: true
toc_float: true
pdf: default
docx: default
```

Note the special syntax (`pdf: default`) if you don't want to override any default options.

To render to all formats specified in the YAML of a document, you can use `output_format = "all"`.

```
quarto::quarto_render("diamond-sizes.qmd", output_format = "all")
```

31.3 Documents

The previous chapter focused on the default `html` output. There are several basic variations on that theme, generating different types of documents. For example:

- `pdf` makes a PDF with LaTeX (an open-source document layout system), which you'll need to install. RStudio will prompt you if you don't already have it.
- `docx` for Microsoft Word (`.docx`) documents.
- `odt` for OpenDocument Text (`.odt`) documents.
- `rtf` for Rich Text Format (`.rtf`) documents.
- `gfm` for a GitHub Flavored Markdown (`.md`) document.
- `ipynb` for Jupyter Notebooks (`.ipynb`).

Remember, when generating a document to share with decision-makers, you can turn off the default display of code by setting global options in document YAML:

```
execute:
echo: false
```

For `html` documents another option is to make the code chunks hidden by default, but visible with a click:

```
format:
html:
code: true
```

31.4 Presentations

You can also use Quarto to produce presentations. You get less visual control than with a tool like Keynote or PowerPoint, but automatically inserting the results of your R code into a presentation can save a huge amount of time. Presentations work by dividing your content into slides, with a new slide beginning at each second (`##`) level header. Additionally, first (#) level headers indicate the beginning of a new section with a section title slide that is, by default, centered in the middle.

Quarto supports a variety of presentation formats, including:

1. `revealjs` - HTML presentation with revealjs

2. `pptx` - PowerPoint presentation

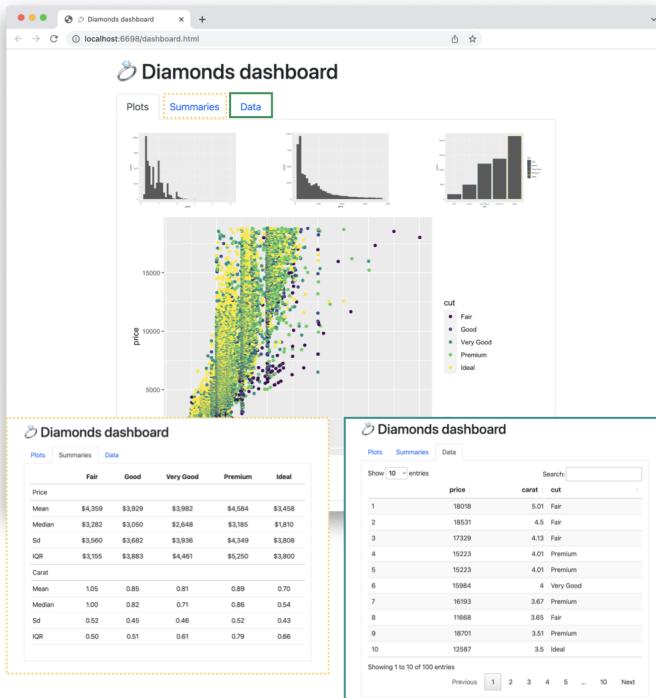

3. `beamer` - PDF presentation with LaTeX Beamer.

You can read more about creating presentations with Quarto at <https://quarto.org/docs/presentations>.

31.5 Dashboards

Dashboards are a useful way to communicate information visually and quickly. A dashboard-like look can be achieved with Quarto using document layout options like sidebars, tabssets, multi-column layouts, etc.

For example, you can produce this dashboard:

Using this code:

```
---
```

```
title: "⌚ Diamonds dashboard"
format: html
execute:
  echo: false
---
```

```
```{r}
#| label: setup
```

```

#| include: false

library(tidyverse)
library(gt)
```

::: panel-tabset
## Plots

```{r}
#| layout: [[30,-5, 30, -5, 30], [100]]

ggplot(diamonds, aes(x = carat)) + geom_histogram(binwidth = 0.1)
ggplot(diamonds, aes(x = price)) + geom_histogram(binwidth = 500)
ggplot(diamonds, aes(x = cut, color = cut)) + geom_bar()

ggplot(diamonds, aes(x = carat, y = price, color = cut)) + geom_point()
```

## Summaries

```{r}
diamonds |>
 select(price, carat, cut) |>
 group_by(cut) |>
 summarize(
 across(where(is.numeric), list(mean = mean, median = median, sd = sd, IQR = IQR))
) |>
 pivot_longer(cols = -cut) |>
 pivot_wider(names_from = cut, values_from = value) |>
 separate(name, into = c("var", "stat")) |>

## Data

```{r}
diamonds |>
 arrange(desc(carat)) |>
 slice_head(n = 100) |>
 select(price, carat, cut) |>
 DT::datatable()
```
```
!!!
```

To learn more about Quarto component layouts, visit <https://quarto.org/docs/interactive/layout.html>.

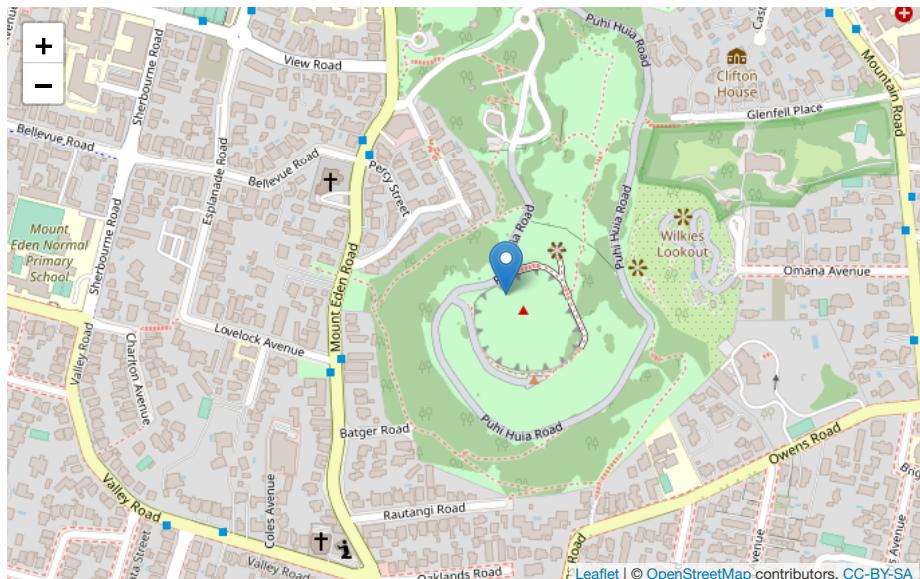

## 31.6 Interactivity

Any HTML document can contain interactive components.

### 31.6.1 htmlwidgets

HTML is an interactive format, and you can take advantage of that interactivity with **htmlwidgets**, R functions that produce interactive HTML visualizations. For example, take the **leaflet** map below. If you're viewing this page on the web, you can drag the map around, zoom in and out, etc. You obviously can't do that in a book, so Quarto automatically inserts a static screenshot for you.

```
library(leaflet)
leaflet() |>
 setView(174.764, -36.877, zoom = 16) |>
 addTiles() |>
 addMarkers(174.764, -36.877, popup = "Maungawhau")
```

The great thing about **htmlwidgets** is that you don't need to know anything about HTML or JavaScript to use them. All the details are wrapped inside the package, so you don't need to worry about it.

There are many packages that provide **htmlwidgets**, including:

- **dygraphs**, <https://rstudio.github.io/dygraphs>, for interactive time series visualizations.
- **DT**, <https://rstudio.github.io/DT/>, for interactive tables.
- **threejs**, <https://bwlewis.github.io/rthreejs> for interactive 3d plots.
- **DiagrammeR**, <https://rich-iannone.github.io/DiagrammeR> for diagrams (like flow charts and simple node-link diagrams).

To learn more about htmlwidgets and see a complete list of packages that provide them visit <https://www.htmlwidgets.org>.

### 31.6.2 Shiny

htmlwidgets provide **client-side** interactivity — all the interactivity happens in the browser, independently of R. On the one hand, that's great because you can distribute the HTML file without any connection to R. However, that fundamentally limits what you can do to things that have been implemented in HTML and JavaScript. An alternative approach is to use **shiny**, a package that allows you to create interactivity using R code, not JavaScript.

To call Shiny code from a Quarto document, add `server: shiny` to the YAML header:

```
title: "Shiny Web App"
format: html
server: shiny
```

Then you can use the “input” functions to add interactive components to the document:

```
library(shiny)

textInput("name", "What is your name?")
numericInput("age", "How old are you?", NA, min = 0, max = 150)
```

And you also need a code chunk with chunk option `context: server` which contains the code that needs to run in a Shiny server.

What is your name?

How old are you?

You can then refer to the values with `input$name` and `input$age`, and the code that uses them will be automatically re-run whenever they change.

We can't show you a live shiny app here because shiny interactions occur on the **server-side**. This means that you can write interactive apps without knowing JavaScript, but you need a server to run them on. This introduces a logistical issue: Shiny apps need a Shiny server to be run online. When you run Shiny apps on your own computer, Shiny automatically sets up a Shiny server for you, but you need a public-facing Shiny server if you want to publish this sort of interactivity online. That's the fundamental trade-off of shiny: you can do anything in a shiny document that you can do in R, but it requires someone to be running R.

For learning more about Shiny, we recommend reading Mastering Shiny by Hadley Wickham, <https://mastering-shiny.org>.

## 31.7 Websites and books

---

With a bit of additional infrastructure, you can use Quarto to generate a complete website or book:

- Put your `.qmd` files in a single directory. `index.qmd` will become the home page.
- Add a YAML file named `_quarto.yml` that provides the navigation for the site. In this file, set the `project` type to either `book` or `website`, e.g.:

```
project:
 type: book
```

For example, the following `_quarto.yml` file creates a website from three source files: `index.qmd` (the home page), `viridis-colors.qmd`, and `terrain-colors.qmd`.

```
project:
 type: website

website:
 title: "A website on color scales"
 navbar:
 left:
 - href: index.qmd
 text: Home
 - href: viridis-colors.qmd
 text: Viridis colors
 - href: terrain-colors.qmd
 text: Terrain colors
```

The `_quarto.yml` file you need for a book is very similarly structured. The following example shows how you can create a book with four chapters that renders to three different outputs (`html`, `pdf`, and `epub`). Once again, the source files are `.qmd` files.

```
project:
 type: book

book:
 title: "A book on color scales"
 author: "Jane Coloriste"
 chapters:
 - index.qmd
 - intro.qmd
 - viridis-colors.qmd
 - terrain-colors.qmd

format:
 html:
 theme: cosmo
 pdf: default
 epub: default
```

We recommend that you use an RStudio project for your websites and books. Based on the `_quarto.yml` file, RStudio will recognize the type of project you're working on, and add a Built tab to the IDE that you can use to render and preview your websites and books. Both websites and books can also be rendered using `quarto::render()`.

Read more at <https://quarto.org/docs/websites> about Quarto websites and <https://quarto.org/docs/books> about books.

## 31.8 Other formats

---

Quarto offers even more output formats:

- You can write journal articles using Quarto Journal Templates:  
<https://quarto.org/docs/journals/templates.html>.
- You can output Quarto documents to Jupyter Notebooks with `format: ipynb`:  
<https://quarto.org/docs/reference/formats/ipynb.html>.

See <https://quarto.org/docs/output-formats/all-formats.html> for a list of even more formats.

## 31.9 Learning more

---

To learn more about effective communication in these different formats, we recommend the following resources:

- To improve your presentation skills, try [\*Presentation Patterns\*](#) by Neal Ford, Matthew McCollough, and Nathaniel Schutta. It provides a set of effective patterns (both low- and high-level) that you can apply to improve your presentations.
- If you give academic talks, you might like the [\*Leek group guide to giving talks\*](#).
- We haven't taken it ourselves, but we've heard good things about Matt McGarrity's online course on public speaking: <https://www.coursera.org/learn/public-speaking>.
- If you are creating many dashboards, make sure to read Stephen Few's [\*Information Dashboard Design: The Effective Visual Communication of Data\*](#). It will help you create dashboards that are truly useful, not just pretty to look at.
- Effectively communicating your ideas often benefits from some knowledge of graphic design. Robin Williams' [\*The Non-Designer's Design Book\*](#) is a great place to start.

 You are reading the work-in-progress second edition of R for Data Science. This chapter should be readable but is currently undergoing final polishing. You can find the complete first edition at <https://r4ds.had.co.nz>.

Earlier, we discussed a basic workflow for capturing your R code where you work interactively in the *console*, then capture what works in the *script editor*. Quarto brings together the console and the script editor, blurring the lines between interactive exploration and long-term code capture. You can rapidly iterate within a chunk, editing and re-executing with Cmd/Ctrl + Shift + Enter. When you're happy, you move on and start a new chunk.

Quarto is also important because it so tightly integrates prose and code. This makes it a great **analysis notebook** because it lets you develop code and record your thoughts. An analysis notebook shares many of the same goals as a classic lab notebook in the physical sciences. It:

- Records what you did and why you did it. Regardless of how great your memory is, if you don't record what you do, there will come a time when you have forgotten important details. Write them down so you don't forget!
- Supports rigorous thinking. You are more likely to come up with a strong analysis if you record your thoughts as you go, and continue to reflect on them. This also saves you time when you eventually write up your analysis to share with others.

- Helps others understand your work. It is rare to do data analysis by yourself, and you'll often be working as part of a team. A lab notebook helps you share not only what you've done, but why you did it with your colleagues or lab mates.

Much of the good advice about using lab notebooks effectively can also be translated to analysis notebooks. We've drawn on our own experiences and Colin Purrington's advice on lab notebooks (<https://colinpurrington.com/tips/lab-notebooks>) to come up with the following tips:

- Ensure each notebook has a descriptive title, an evocative file name, and a first paragraph that briefly describes the aims of the analysis.
- Use the YAML header date field to record the date you started working on the notebook:

```
date: 2016-08-23
```

Use ISO8601 YYYY-MM-DD format so that's there no ambiguity. Use it even if you don't normally write dates that way!

- If you spend a lot of time on an analysis idea and it turns out to be a dead end, don't delete it! Write up a brief note about why it failed and leave it in the notebook. That will help you avoid going down the same dead end when you come back to the analysis in the future.
- Generally, you're better off doing data entry outside of R. But if you do need to record a small snippet of data, clearly lay it out using `tibble::tribble()`.

- If you discover an error in a data file, never modify it directly, but instead write code to correct the value. Explain why you made the fix.
- Before you finish for the day, make sure you can render the notebook. If you’re using caching, make sure to clear the caches. That will let you fix any problems while the code is still fresh in your mind.
- If you want your code to be reproducible in the long-run (i.e. so you can come back to run it next month or next year), you’ll need to track the versions of the packages that your code uses. A rigorous approach is to use `renv`, <https://rstudio.github.io/renv/index.html>, which stores packages in your project directory. A quick and dirty hack is to include a chunk that runs `sessionInfo()` — that won’t let you easily recreate your packages as they are today, but at least you’ll know what they were.
- You are going to create many, many, many analysis notebooks over the course of your career. How are you going to organize them so you can find them again in the future? We recommend storing them in individual projects, and coming up with a good naming scheme.

R for Data Science (2e) was written by Hadley Wickham, Mine Çetinkaya-Rundel, and Garrett Grolemund.

This book was built with [Quarto](#).
